## **ABSTRACT**

Obesity, diabetes, and associated co-morbidities are part of a major health epidemic in the United States, and they are becoming more rampant globally as well. Much still remains to be understood regarding the intricate mechanisms controlling whole-body energy balance and how dysregulation leads to disease. Regular exercise benefits systemic health, and it is hypothesized that myokines secreted from contracting skeletal muscle can mediate these effects. To identify novel exercise-regulated myokines, we measured the levels of 66 cytokines in serum and in glycolytic and oxidative muscles from wildtype mice subjected to either a sprint, endurance run, or one week of voluntary wheel running. Overall, many significant changes were observed in both serum and muscle in response to exercise, and our study identified 22 novel exercise-regulated myokines. Additionally, this is the first report comparing the cytokine profiles between muscle fiber types in response to different exercise regimes, and we demonstrated that there were more differences than commonalities between oxidative and glycolytic muscle. Lastly, a subset of the cytokine changes observed in circulation did not reflect changes in the skeletal muscle but rather correlated with gene expression changes in adipose tissue or liver. In another study, we focused on elucidating the role of a specific myokine, myonectin, in regulating systemic energy metabolism using a genetic knockout mouse model. Loss of myonectin had minimal or negligible effects on glucose metabolism, lipid metabolism, and exercise capacity in male and female mice fed a control, low-fat diet. However, when challenged with a high-fat diet to induce obesity, myonectin deficiency altered lipid handling and storage in males. Specifically, knockout mice exhibited a striking impairment in clearing serum lipids following a meal or oral lipid gavage compared to their wildtype littermates. Additionally, myonectin deficiency resulted in a dramatic reduction of high-fat diet-induced hepatic steatosis and, in parallel, a significant increase in adipose tissue mass

with concomitant adipocyte hypertrophy. The increased adiposity in knockout mice was promoted, in part, through increased adipose tissue lipoprotein lipase activity. In sum, our studies highlight novel and important functions of myokines in exercise and lipid metabolism, linking skeletal muscle to systemic energy homeostasis.

## ACKNOWLEDGEMENTS

I would like to start by acknowledging those who supported my research beginnings – Dr. Zhibin Guan and Dr. Hanxiang Zeng. I am extremely thankful to Dr. Guan for the opportunity to conduct research as an undergraduate in his lab at UC Irvine. Hanxiang, a PhD student at the time, was patient, kind, and an incredible mentor. My experience in this lab instilled in me a love for conducting basic research.

I am extremely grateful for the mentorship of my current PI, Dr. Will Wong, and the opportunity to conduct my PhD research in his lab. His enthusiasm for science is unrivaled, making his lab an enjoyable and exciting place to work. I especially appreciate his balance in mentoring style; he was always available and happy to provide guidance, but he also allowed me the freedom to explore, which expedited my growth as a scientist. I also value his level of trust in me as a scientist and in my data, and his principle to follow the data and not get distracted based on what we *a priori* expected the results to say. Overall, Will's guidance was instrumental in my scientific development.

I could not have asked for better labmates to have worked with over the years, including Marcus, Stefanie, Pia, Risa, Susie, Shelley, Ashley, Dylan, Gel, and Francesca. I really enjoy how collaborative our lab is and that my peers were always willing to help me with a mouse experiment or brainstorm with me about complicated data. Not only do I appreciate their scientific help and insight, but they are an incredibly friendly and fun group of people that I enjoyed spending many hours with.

I am still amazed at how quickly my BCMB classmates and I bonded and became very close friends. Their friendship has been incredibly important to me. Not only did we provide a framework of support for one another, but we had an amazingly fun time during grad school. They

will undoubtedly be friends for life. The same is true for other friends I met during graduate school, including those in CBI whom I met through Rick, climbing friends, and yoga friends. I am also thankful for the support and encouragement of my friends from High School and Undergrad, some of whom made the long trip to Baltimore to visit me during my years here.

Of course, I owe much of my success and my happiness in life to the love and support of my family. I cannot express in words my gratitude for everything they have done and continue to do for me. Thank you, Mama, Papa, Kim, Meghan, and Brittany! And thank you to my future in-laws for supporting me as if I'm already part of the family!

Lastly, thank you to my fiancé, Rick Hooy. You encourage me to pursue my dreams, you help me celebrate the successes, and you support me during hardship. I could not have done this without you.

# **CHAPTER 1:**

## **Introduction**

## **Obesity, diabetes, and associated co-morbidities**

The recent dramatic increase in the prevalence of obesity is alarming, with recent estimates categorizing nearly 40% of adults and more than 18% of children in the United States as clinically obese (1). Approximately 13% of the world's population is obese, a figure which has nearly tripled in the last four decades (2). It is widely accepted that obesity is causally related to the development of comorbidities such as type 2 diabetes and cardiovascular disease, both of which are among the leading causes of death in the United States (3–6). Not only do these metabolic health issues have a negative impact on the well-being of affected individuals, but also they pose an enormous economic burden on society (5–7). There is a dire need to understand the basic biology underlying metabolic dysregulation associated with excess caloric intake and a sedentary lifestyle, novel findings of which may lead to innovative treatments or preventative measures.

## **Systemic control of energy homeostasis**

Controlling energy homeostasis is a complex, systems-level task for an organism. Fundamentally, this requires balancing food intake and energy expenditure to promote survival in times of fluctuating energy supply and demand. To do so, the body has to adapt its metabolism to its current metabolic state. For example, feeding stimulates anabolic processes to promote nutrient storage whereas fasting is dominated by catabolic processes to break down stored nutrients for energy utilization (8, 9). Exercise presents a unique metabolic challenge to an animal whereby high energy substrates are directed to the working skeletal muscle for ATP production, and fuel selection is dependent on exercise intensity (8). Proper control of nutrient intake, storage, and utilization specific to the metabolic state is dependent on the ability of different organs and organ systems to communicate their status and needs to other parts of the body. This inter-organ crosstalk

is mediated by nutrient flow, neuronal signals, and the endocrine system. Integration of these signals results in activation or suppression of specific metabolic pathways in a tissue-specific manner to maintain whole-body metabolic homeostasis. (8, 9). Secreted proteins represent a major part of the endocrine system, and greater than 10 percent of all protein-coding genes in the human genome are predicted to be secreted proteins based on the presence of a signal peptide (10). Most major metabolic organs are capable of both receiving endocrine signals as well as producing secreted proteins for inter-organ communication, including the gut, liver, adipose, and skeletal muscle (9). When energy balance is perturbed by overconsumption of calories and a sedentary lifestyle, the resulting disruption of signaling pathways regulated by these circulating hormones not only exacerbates the metabolic phenotype but also can lead to the development of comorbidities (11). Thus, studying the function of secreted proteins in normal physiology and metabolic disease may facilitate the discovery of novel therapeutic targets or strategies.

## **Myokines**

Proteins secreted from the skeletal muscle are called myokines, and they can act in an autocrine, paracrine, and/or endocrine manner (12). Myostatin was the first characterized myokine, and it was discovered in the process of identifying new transforming growth factor beta (TGF- $\beta$ ) superfamily members. It is most well-known for its autocrine and paracrine roles as a negative regulator of muscle growth (13). Since then, numerous other myokines have been identified and characterized, spanning diverse roles in physiology. These include interleukin (IL)-7, IL-8, leukemia inhibitory factor (LIF), IL-15, brain-derived neurotrophic factor (BDNF), irisin, fibroblast growth factor 21 (FGF21), decorin, and secreted protein acidic and rich in cysteine (SPARC), among others (14, 15). Many proteomic studies have been carried out to characterize

the entire skeletal muscle secretome. Depending on the experimental design and method used, most of these studies have estimated that there are hundreds of myokines actively produced and secreted by skeletal muscle (16–20); hence, many remain to be characterized.

### **Myokines and exercise**

Well before the discovery of myostatin, the existence of myokines was postulated, specifically in the context of exercise; it was hypothesized that exercising skeletal muscle must secrete some “exercise factor” into circulation in order to explain the observations that exercise is sufficient to reduce blood glucose by promoting glucose uptake and utilization in both exercising and non-exercising skeletal muscle, and that these effects are independent of the nervous system (21). Regular exercise is protective against many diseases, including cardio-metabolic disorders, whereas physical inactivity is a major risk factor for disease and premature mortality (15). However, the underlying mechanisms linking the inverse relationship between exercise and disease are not fully understood. Thus, there have been major efforts to identify “exercise factors” or “exerkines” which may mediate the beneficial health effects of exercise. Interleukin-6 (IL-6), the most extensively studied myokine, was the first protein shown to be secreted from contracting skeletal muscle. In the context of exercise, it functions in an endocrine manner to mobilize energy substrates and then in an autocrine fashion to promote substrate uptake and utilization in the skeletal muscle (15). However, in the context of injury or infection, IL-6 functions as a pro-inflammatory molecule and plays a role in activating the adaptive immune response (22). In addition to acute inflammation, elevated baseline IL-6 levels are partly responsible for chronic low-grade inflammation that is characteristic of obesity and type 2 diabetes (23). With regular exercise, resting levels of IL-6 are actually decreased while expression of the receptor IL-6Ra is

upregulated, thereby increasing IL-6 sensitivity and preventing IL-6-mediated chronic inflammation (15). Thus, IL-6 is a prime example of a myokine with acute functions in exercise that mechanistically links chronic exercise with improved health.

### **Finding novel exercise-induced myokines**

Various approaches have been taken to identify novel exercise-induced myokines that could mediate the beneficial effects of exercise, similarly to IL-6. One method is *in vitro* studies using differentiated myotubes in culture that are stimulated to contract with electrical pulses. The conditioned media is then examined with proteomics methods to identify secreted proteins (24). The major advantage to this approach is the ability to detect *bona-fide* myokines; whatever was detected in the media came *directly* from the muscle cells. However, cell culture is an imperfect mimic of skeletal muscle *in vivo*: the organ is comprised of other cell types in addition to myotubes, electrical pulse stimulation does not fully reproduce the physiological changes exhibited in contracting skeletal muscle, and not all local and systemic factors that interact with the muscle are represented *in vitro* (24, 25). There have also been many human studies. Most often, blood and muscle biopsies are taken before and after exercise and subjected to transcriptomics or proteomics to identify changes induced by exercise (24). One drawback to human studies is that muscle biopsies are most often taken from a large leg muscle like the vastus lateralis, which contains a mix of muscle fiber types, so it is not feasible to determine the contribution of individual muscle fiber types (24). Additionally, it is not practical in humans to take tissue samples from other metabolic organs to assess if changes seen in the serum are due to protein expression and secretion in non-muscle tissues as a secondary response to myokine signaling from the exercising skeletal muscle. In general, a major limitation to the traditional proteomics approach using mass

spectrometry is that it is not sensitive enough to detect factors that are at very low abundance (25). Many circulating factors in the serum are known to be in the ng/mL or even pg/mL range and thus would not even be detected by these methods even though small changes in concentration of some circulating proteins are known to exert significant biological effects (25). Lastly, many *in vitro* and *in vivo* studies rely on mRNA expression data only and infer that those changes reflect protein levels, which may produce misleading conclusions (25). Chapter 2 describes a study that overcomes many of these limitations and provides novel insights regarding exercise-regulated changes in secreted proteins.

### **Adiponectin and C1q/TNF Related Proteins (CTRPs)**

While the focus of the study detailed in Chapter 2 is on finding novel myokines, Chapter 3 describes a study characterizing the physiological role of a particular myokine called complement component 1q (C1q)/tumor necrosis factor (TNF)-related protein 15 (CTRP15). CTRP15 is part of the CTRP family of secreted proteins. CTRPs were first discovered in 2004 from a database of expressed sequence tags based on homology to adiponectin (26). Adiponectin is an extensively studied adipokine (hormone secreted from the adipose tissue) having pleiotropic roles in metabolism. The hormone sensitizes the body to insulin by stimulating AMP-activated protein kinase (AMPK) signaling in liver and skeletal muscle to enhance fat oxidation and glucose uptake and reduce hepatic gluconeogenesis (27). Despite being almost exclusively expressed in and secreted from adipose tissue, circulating adiponectin levels are paradoxically reduced in obese humans and mice (28, 29). The same holds true for diabetic patients (30). In fact, studies suggest that adiponectin can be a causative link between obesity and metabolic co-morbidities: a combination of genetic factors (e.g. single-nucleotide polymorphisms (SNPs) in the adiponectin

gene) and environmental factors that lead to obesity (e.g. high-fat diet) result in lower adiponectin levels, and adiponectin action is further decreased due to lower expression of its receptors in the obese state. This reduction in adiponectin action has been causatively linked to the development of insulin resistance, type 2 diabetes, metabolic syndrome, and atherosclerosis (27). Given the significant role adiponectin plays in metabolism and the etiology of metabolic diseases, the impetus to study the novel family of adiponectin paralogs in the context of metabolism was obvious.

### **CTRP structure**

CTRPs share the same domain structure as adiponectin: an N-terminal signal peptide to promote secretion, a short variable domain with one or more conserved cysteine residues, a collagen-like domain, and a C-terminal globular c1q domain (**Fig. 1**) (11). The c1q domain is homologous to the complement protein of the same name and is structurally similar to TNF $\alpha$ , inspiring the name of the protein family (C1q/TNF related protein) (26). All CTRPs form trimers and many form higher order oligomeric structures, the formation of which is mediated by disulfide bond formation between conserved cysteine residues in the variable N-terminal domain (11). Different oligomeric forms of adiponectin have been shown to have different functions *in vivo* (31). Whether the same holds true for CTRPs remains largely unexplored. The exception is CTRP12 in which different isoforms form different oligomeric complexes and preferentially activate different signaling pathways: the full-length isoform forms trimers and larger complexes and activates protein kinase B (AKT) signaling whereas the cleaved, globular isoform forms dimers and activates mitogen-activated protein kinase (MAPK) signaling (32). Interestingly, many CTRPs have been shown to form hetero-oligomeric complexes with other CTRPs or with

**Figure 1. Schematic of CTRPs.** With the exception of CTRP4, every CTRP consists of four domains: a signal peptide for secretion (*dark grey*), an N-terminal domain with one or more conserved Cys residues (*white*), a collagen domain with varying numbers of Gly-X-Y repeats (*light gray*), and a C-terminal globular domain homologous to the immune complement C1q (*blue*). The numbers on the right refer to the percent amino acid identity between human and mouse orthologs when comparing the full-length protein (first column) or the C-terminal globular domain (second column). CTRP4 and CTRP8 are omitted – the former consists of only two tandem C1q domains, while the latter is absent in the mouse genome. **(figure and figure legend copied with permission from reference 11)**

adiponectin (33–38); the physiological significance is currently unknown but it is possible that hetero-oligomers function in a manner different from the homo-oligomers, which would functionally increase the CTRP gene-to-ligand ratio (33). Many CTRPs are also glycosylated, which is likely to be important for protein folding in the endoplasmic reticulum, stability, and secretion (39). However, the functional significance of post-translational modifications of CTRPs has not been explored, with the exception of CTRP12. Cleavage of CTRP12 to generate the

globular isoform is regulated, in part, by N-linked glycosylation on a conserved asparagine residue in close proximity to the cleavage site (40).

### **CTRP function**

All CTRPs are highly conserved throughout vertebrate evolution, implicating that each has a significant role in biology (11). Like adiponectin, many CTRPs are expressed in and secreted from white adipose tissue, but in general their tissue expression profiles in mice and humans are broader than that of adiponectin (11). For most CTRPs, expression and/or circulating levels are altered by acute or chronic metabolic state in mice ([reviewed in 11], 41–45). The functional roles of CTRPs have begun to be elucidated using overexpression and knockout mouse models. As expected based on homology to adiponectin, many of these mouse models have significant metabolic phenotypes, including differences in body weight (42, 46, 47), glucose homeostasis (44, 45), lipid homeostasis, or both glucose and lipid metabolism (41, 43, 46–48) (metabolic phenotypes also reviewed in 11). The relevance to human physiology has been confirmed with studies that have correlated serum or tissue CTRP levels with metabolic state or metabolic pathology including obesity, type 2 diabetes, and/or non-alcoholic fatty liver disease ([reviewed in 11], 43–45, 49–58). With an increasing focus on investigating CTRP function using rodent models, many CTRPs have been found to have physiological roles outside of nutrient metabolism, including inflammation (44, 45, 59), cardiac function (60–64), blood pressure (65), kidney function (data in press), bone function (66), atherogenesis (67–69), tissue fibrosis (45, 62), vascular remodeling (70), neuroinflammation/brain function (71), autophagy (72), and iron metabolism (73–75) (non-metabolic phenotypes also reviewed in 11). In humans, tissue or serum levels of CTRPs have been associated (positively or negatively) with the following disease states

in addition to nutrient metabolism: congestive heart failure (76), coronary artery disease (67, 77), late onset retinal degeneration, pulmonary arterial hypertension (78), polycystic ovarian syndrome (79), and anemia (80–82) (non-metabolic disease states correlated with CTRPs also reviewed in 11). One major limitation to the study of CTRP function is that there is limited research regarding their receptors. CTRP8 was shown to bind to and activate the G-protein-coupled receptor (GPCR) relaxin receptor 1 (RXFP1) in human glioblastoma cells, inducing cell migration and production of cathepsin B, a lysosomal protease correlated with tumor invasion (83). This interaction outside of the context of glioblastoma has not been investigated. CTRP9 can activate adiponectin receptor 1 (AdipoR1) to promote vasorelaxation in mouse aorta, which may have implications in endothelial dysfunction in cardiovascular disease (84). Lastly, CTRPs 10, 11, 13, and 14 were shown to bind to brain-specific angiogenesis inhibitor 3 (BAI3), a cell-adhesion GPCR, and the c1q globular domains were sufficient to decrease the excitatory synapse density in cultured neurons (85). However, the *in vivo* physiological relevance has not yet been determined. Given the diverse roles of the CTRP family of proteins and their relevance to so many disease states, further study of CTRP function and elucidation of relevant receptors will not only provide insight into normal physiology but also may provide a basis for therapeutic strategies aimed at developing receptor agonists or antagonists.

### **CTRP15/myonectin/erythroferrone**

CTRP15 is unique among the CTRP family in that it is almost exclusively expressed in skeletal muscle in both humans and mice in normal conditions (38) whereas other members display a broader expression profile (11). For this reason, CTRP15 is also referred to as “myonectin.” Interestingly, the expression of most known myokines is not restricted to the skeletal muscle but

rather they are more widely expressed, so it seems myonectin is unique among myokines in its very limited expression profile under basal conditions (38). Myonectin expression in the skeletal muscle is upregulated after exercise (38, 64), and mouse studies have linked this exercise-induced increase in myonectin with improved outcomes after myocardial ischemia-reperfusion injury (64). However, during stress erythropoiesis in mice stimulated by blood loss or erythropoietin (EPO) administration, myonectin is highly induced in erythroblasts in the bone marrow and spleen (75). Under these circumstances, myonectin signals to the liver to suppress hepcidin expression, a negative regulator of iron mobilization, thereby increasing iron availability for new red blood cells (75). Based on this discovery, myonectin is also referred to as “erythroferrone” (75). The relevance to iron metabolism in humans has also been demonstrated. In patients with anemia due to chronic kidney disease, serum levels of myonectin rise in response to EPO or erythropoiesis-stimulating agents (86, 87). Similarly, blood loss or EPO administration to healthy individuals is sufficient to increase circulating levels of myonectin (81). Basal levels of myonectin are higher in patients with iron deficiency anemia (80) and beta thalassemia (81), and lower in patients with anemia of inflammation (82), implying myonectin’s involvement in pathogenesis or response to anemia diseases.

The first piece of evidence for myonectin’s role in nutrient metabolism is its unique expression pattern in mice based on metabolic state: mRNA and circulating levels are at low, basal levels during fasting but are dramatically upregulated upon re-feeding following an overnight fast (38). Interestingly, it seems that any nutrient flux through the muscle is sufficient to stimulate the expression and release of myonectin – both lipid and glucose administration are independently sufficient to show the same effect both *in vivo* and in cultured myotubes (38). In line with its postprandial expression pattern, myonectin stimulates nutrient uptake into peripheral tissues:

injection of recombinant myonectin into wildtype mice is sufficient to lower serum free fatty acid levels, and myonectin acts directly on adipocytes and hepatocytes in culture to stimulate fatty acid uptake from the media (38). Additionally, myonectin serves as a postprandial cue to stimulate the mammalian target of rapamycin (mTOR) pathway in the liver to inhibit autophagy, an intracellular recycling process that is activated during fasting (72). In humans, serum levels of myonectin have been correlated with metabolic pathologies: myonectin is higher in patients with metabolic syndrome than controls (57), and people with newly diagnosed type 2 diabetes have more myonectin than those with impaired glucose tolerance who, in turn, have higher myonectin than control patients (58). So far, these myonectin studies with respect to metabolism have been limited to recombinant protein infusion into mice, *in vitro* experiments using immortalized cell lines, and human correlational studies. Chapter 3 describes a study that investigates the *in vivo* physiological function of myonectin in regulating metabolic homeostasis in normal physiological conditions or in the context of metabolic disease using a genetic loss-of-function mouse model.

Little, H. C., Tan, S. Y., Cali, F., Rodriguez, S., Lei, X., Wolfe, A., Hug, C., and Wong, G. W. (2018) Multiplex Quantification Identifies Novel Exercise-regulated Myokines/Cytokines in Plasma and in Glycolytic and Oxidative Skeletal Muscle. *Mol Cell Proteomics* **17**, 1546–1563

## ABSTRACT

Exercise is known to confer major health benefits, but the underlying mechanisms are not well understood. The systemic effects of exercise on multi-organ systems are thought to be partly due to myokines/cytokines secreted by skeletal muscle. The extent to which exercise alters cytokine expression and secretion in different muscle fiber types has not been systematically examined. Here, we assessed changes in 66 mouse cytokines in serum, and in glycolytic (plantaris) and oxidative (soleus) muscles, in response to sprint, endurance, or chronic wheel running. Both acute and short-term exercise significantly altered a large fraction of cytokines in both serum and muscle, twenty-two of which are considered novel exercise-regulated myokines. Most of the secreted cytokine receptors profiled were also altered by physical activity, suggesting an exercise-regulated mechanism that modulates the generation of soluble receptors found in circulation. A greater overlap in cytokine profile was seen between endurance and chronic wheel running. Between fiber types, both acute and chronic exercise induced significantly more cytokine changes in oxidative compared to glycolytic muscle. Further, changes in a subset of circulating cytokines were not matched by their changes in muscle, but instead reflected altered expression in liver and adipose tissues. Lastly, exercise-induced changes in cytokine mRNA and protein were only minimally correlated in soleus and plantaris. In sum, our results indicate that exercise regulates a large number of cytokines whose pleiotropic actions may be linked to positive health outcomes. These data provide a framework to further understand potential crosstalk between skeletal muscle and other organ compartments.

## INTRODUCTION

Physical inactivity is a major risk factor contributing to cardio-metabolic disorders in modern society (1, 2). Conversely, regular exercise confers systemic health benefits (3-6). The underlying mechanisms responsible for the positive physiological effects of exercise, however, are not well understood (7, 8). The systemic effects of exercise on multi-organ systems has long thought to be, at least in part, due to myokines and cytokines secreted by skeletal muscle in response to exercise (9-11). These exercise-induced myokines are believed to mediate crosstalk between skeletal muscle and other organ compartments. Depending on the method used and biological contexts, proteomics-based analyses of the muscle “secretome” have identified hundreds of proteins secreted by muscle cells (12-19). The functions for most of these muscle-derived secretory proteins are poorly defined, and it is unclear whether their expression and secretion are regulated by muscle contraction *in vivo*. Importantly, biologically potent molecules, such as cytokines, that normally exist at low levels (typically in the ng/mL and pg/mL range) are generally not detected by current proteomics methods.

The cytokine interleukin (IL)-6 is one of the first myokines shown to be actively secreted by contracting skeletal muscle in human (20, 21). Since its discovery, other cytokines such as IL-7 (22), IL-15 (23), leukemia inhibitory factor (LIF) (24), and vascular endothelial growth factor (VEGF) (25) have also been shown to be functionally relevant exercise-induced myokines, either acting in an autocrine/paracrine manner within muscle, or acting via an endocrine fashion to affect biological processes in non-muscle tissues. Recent *in vitro* studies using electrical pulse stimulation of primary human myotubes and antibody-based detection approaches also identified significant numbers of contraction-induced myokines/cytokines (26, 27). While these *in vitro* studies allow the unequivocal identification of *bona fide* muscle cell-derived myokines, limitations

to these cell models have also been noted. Although differentiated primary myotubes in culture serve as a reasonable proxy for mature muscle cells, they do not capture the three-dimensional muscle fibers in the context of other potentially important accessory cell types (e.g., vascular endothelial cells, satellite cells, immune cells, and sympathetic nerve cells), nor do the cultured myotubes fully resemble the metabolically distinct glycolytic and oxidative fiber types. Further, electrical pulse stimulation of myotubes does not fully recapitulate both the stimulatory and inhibitory pathways induced by exercising skeletal muscle (28). As such, *in vivo* studies in humans or animal models will complement and extend the *in vitro* studies, enabling a more complete understanding of skeletal muscle's response to exercise.

Cytokines, chemokines, and secreted cytokine receptors constitute a large family of secretory proteins with pleiotropic immune and non-immune functions (29-33). As such, changes in local and systemic levels of these molecules in response to exercise could potentially account, at least in part, for the positive effects of physical activities. The present study aimed to address three related questions. First, while a handful of cytokines has thus far been shown to be secreted by exercising muscle *in vivo*, the extent to which different types of physical activity (sprint, endurance, voluntary wheel running) regulates cytokine expression and secretion in glycolytic versus oxidative muscle fibers has not been systematically examined. Most human exercise studies examined transcriptional and protein changes in vastus lateralis, a quadriceps muscle with mixed fiber types. The metabolism of *in vitro* differentiated primary human myotubes also tended to be glycolytic rather than oxidative. Thus, the use of mouse exercise models allows us to address questions that are difficult to study in humans and primary cell culture system. Secondly, it is generally assumed that changes in serum cytokine in response to exercise are directly related to changes in their expression and secretion in skeletal muscle. It remains unknown to what extent

the changes in plasma cytokine levels are due to secondary adaptive changes in their expression and secretion in non-muscle tissues in response to exercise. This could potentially occur if the primary exercise-induced cytokines in turn stimulate the expression and secretion of secondary cytokines in other non-muscle tissues. Thirdly, several transcriptomics studies have been carried out to look at changes in human muscle gene expression in response to exercise (34-37). Whether changes in mRNA level translate into changes in protein level in human skeletal muscle are often not examined, in large part limited by the availability of protein-specific antibodies and the cost of validating a large number of candidate proteins.

With the use of the conventional ELISA method, it is not feasible to simultaneously measure the levels of large numbers of cytokines in a mouse due to limited blood volume that could be sampled. Technological advancement in recent years has made it feasible now to simultaneously quantify a large number of cytokines in serum and tissues using only small volume of blood or quantity of tissue. Using a bead-based multiplex profiling method, we seek to measure cytokine levels in mice in response to an acute sprint or endurance run, or a short-term access to a running wheel for one week (representing chronic exercise). Here, we examined a total of 66 known cytokines (including secreted cytokine receptors and acute phase proteins) that represent a well-studied set of molecules with diverse functions and activities. These cytokines act on diverse cell types to modulate a variety of biological processes that include inflammation, chemotaxis, apoptosis, metabolism, angiogenesis, and cell proliferation (38). Given the pleiotropic systemic effects of exercise, we hypothesized that acute and chronic exercise would dynamically alter cytokine levels in circulation and in different muscle fiber types (e.g., oxidative and glycolytic). Indeed, our results show that exercise modulates the expression of a large number of cytokines in different muscle fiber types depending on the type of physical activity (sprint, endurance, or

chronic wheel running). Many of these cytokines are considered novel exercise-regulated myokines. Concordance between mRNA and protein level was observed for only a small subset of cytokines. Further, we showed that a subset of circulating cytokines is likely induced and secreted in non-muscle tissues in response to exercise, highlighting the primary skeletal muscle response to exercise and the secondary adaptive response in non-muscle tissues.

## **EXPERIMENTAL PROCEDURES**

### **Animals**

Eight-week-old C57BL/6J male mice were purchased from The Jackson Labs. All mice were housed in polycarbonate cages under a 12:12-h light-dark photocycle (6 AM – 6 PM) and had access to food and water *ad libitum* throughout the study period. Mice were allowed to acclimate for one week before experimentation. All animal experiments were approved by the Animal Care and Use Committee of The Johns Hopkins University School of Medicine.

Mice were randomly divided into 4 groups of 10 mice for the following control or exercise paradigms: sedentary, sprint exercise, endurance exercise, and voluntary exercise. At 9 weeks of age, blood was collected from the tail vein for pre-exercise measurements from all mice, including the sedentary group. While serum samples from the sedentary group were not used for analysis, blood was still collected from this group to normalize treatment and handling among all groups. Samples were collected at the same time of day for all mice (10:30 AM). Serum was separated using Microvette® CB 300 LH (The SARSTEDT Group, Numbrecht, Germany), and separated serum was stored at -80°C until analysis.

For sprint and endurance exercise conditions, mice were acclimatized to the treadmill (Exer 3/6 treadmill; Columbus Instruments) for 3 days before the exercise test as follows: day 1: mice

were placed on the stationary treadmill for 10 min (with the shock grid on); day 2: mice were run on the treadmill at a speed of 5 m/min for 10 min at a 10° incline; day 3: mice were run on the treadmill at 10 m/min for 10 min at a 10° incline. A shock grid at the back of the treadmill encouraged mice to continue running by administering a mild shock each time they stepped off the belt. The acute exercise tests were performed on the fourth day when the mice were 10 weeks of age.

**Sprint exercise:** Baseline blood glucose and lactate levels were measured with glucose and lactate meters (Nova Biomedical) from a drop of blood obtained through the tail vein. Mice were run on the treadmill set to a fixed incline of 15° until exhaustion using the following speed protocol: 5 m/min for 1 min, 10 m/min for 2 min, then 2 min intervals of the following speeds (m/min): 10, 14, 18, 22, 26, 28, 30, 32, 34, 36, 38, 40. Mice were run in multiple groups beginning at 9:30 AM. A mouse was considered exhausted when it remained on the shock grid for 5 continuous seconds and, after being blown by one puff of air at 5 sec, still didn't move back to treadmill within 2 sec of the air puff. Immediately after finishing the run, blood glucose and lactate levels were measured (**Table 1**). Within 5 min of finishing the run, mice were anesthetized with isoflurane, euthanized with cervical dislocation, and the following tissues were collected: blood from the retro-orbital sinus via heparin-coated capillary tubes (Fisher 22-362-566), soleus, plantaris, and gastrocnemius muscles, visceral (epididymal) and subcutaneous (inguinal) white adipose tissue, and liver. Separated serum and tissues were flash frozen in liquid nitrogen, and all samples were stored at -80°C until analysis.

**Endurance exercise:** Baseline blood glucose and lactate levels were measured and then mice were run on the treadmill at a fixed incline of 10° until exhaustion using the following speed protocol: 10 m/min for 30 min, then an increase of 2 m/min every 15 min thereafter. Mice were

run in multiple groups beginning at 9:30 AM. Mice were considered exhausted using the same criteria as detailed above. After measuring post-run glucose and lactate values (**Table 1**), mice were euthanized within 5 min of finishing the run and tissues were collected in the same manner as described above.

|                         | Body weight (g) | Pre-exercise Glucose (mg/dL) | Pre-exercise Lactate (mM) | Total run Time (min) | Total run distance (m) | Post-exercise Glucose (mg/dL) | Post-exercise Lactate (mM) |
|-------------------------|-----------------|------------------------------|---------------------------|----------------------|------------------------|-------------------------------|----------------------------|
| Sprint                  | 25.7 ± 0.6      | 186 ± 6                      | 2.0 ± 0.3                 | 11 ± 1               | 156 ± 20               | 199 ± 9                       | 11.0 ± 0.6                 |
| Endurance run           | 26.6 ± 0.6      | 176 ± 5                      | 3.0 ± 0.4                 | 72 ± 5               | 912 ± 85               | 210 ± 6                       | 5.5 ± 0.3                  |
| Voluntary wheel running | 25.7 ± 0.5      | 183 ± 5                      | --                        |                      |                        |                               |                            |
| Sedentary               | 25.3 ± 0.4      | 193 ± 6                      | 2.3 ± 0.2                 |                      |                        |                               |                            |

**Table 1. Body weight, total run time and distance, and pre- and post-exercise blood glucose and lactate levels.** All values shown as average ± S.E. N=10 mice per group.

Voluntary exercise: At 10 weeks of age, mice were separated into individual cages and a running wheel (Columbus Instrument) was placed in each cage such that mice had free access to it. This represents a form of chronic exercise. After one week, mice were sacrificed and tissues were collected as described above. Running wheels were left in the cages until the time of sacrifice (10:30 AM).

Sedentary control: At 10 weeks of age, mice that were normally housed in the cage (with no running wheel) were sacrificed and tissues were collected as described above. Mice were sacrificed at 10:00 AM.

Throughout the study, all mice were treated in the exact same manner, with the exception of the exercise itself, to facilitate accurate analysis by minimizing any potential confounding factors.

### **Muscle lysate preparation**

One plantaris and one soleus muscle from each mouse was used. Muscles were lysed in 500  $\mu$ L PBS supplemented with protease inhibitor cocktail (Sigma). First, muscles were homogenized with a 1 mL glass dounce homogenizer (Wheaton), using the loose pestle followed by the tight pestle. Subsequently, the suspension was subjected to sonication to complete the tissue lysis (Branson Sonifier 150; 5-10 s at the lowest setting). Homogenates were centrifuged at 12,000 x g for 20 min at 4°C and the supernatant was transferred to a new tube. Total protein content in the supernatant was quantified with a Bradford protein assay (Sigma), and the cleared lysate was stored at -80°C until analysis.

### **Multiplex assays for measuring cytokine protein level**

Multiplex assays for 66 mouse cytokines (covering the majority of the well-studied cytokines) were performed using a Luminex bead-based multiplex system according to manufacturer's protocol (EMD Millipore, Billerica, MA). This method is sensitive and reproducible (39, 40) and has been validated in multiple studies (27, 41). The following 4 assay kits (covering 66 analytes according to their dynamic range) from Millipore were used to measure the concentrations of cytokines in mouse serum, soleus homogenate, and plantaris homogenate: MCYTOMAG-70K, MECY2MAG-73K, MSCRMAG-42K, and MTH17MAG-47K. IFN- $\gamma$  protein levels in soleus and plantaris were measured with the kit MCYTOMAG-70K. However, IFN- $\gamma$  levels in serum were measured using a more sensitive assay kit MECY2MAG-73K. Many cytokine receptors are known to be proteolytic cleaved and the soluble ligand-binding ectodomain circulates in plasma (42). Thus, secreted sCD30, sIL-1RI, sIL-1RII, sIL-2Ra, sIL-4R, sIL-6R, sTNFR1, sTNFR2, sVEGFR1, sVEGFR2, sVEGFR3, sgp130, and sRAGE were also measured as

part of the 66 cytokines profiled. The experiments were set up according to the manufacturer's protocol and the assays were performed as we have previously described (43). In brief, standards were provided for each mouse cytokine, from which standard curves were generated. Serum was diluted according to the manufacturer's protocol and cleared muscle lysates were assayed undiluted. For soleus lysates, an average of  $18.05 \pm 6.79$  pg protein was added per well, and for plantaris lysates, an average of  $38.84 \pm 10.43$  pg protein was added per well. All samples (n=10 mice per group) and standards were analyzed using a Luminex 200 instrument (Luminex, Austin, TX) and XPonent 3.1 Software (Millipore, Billerica, MA). Concentrations were determined for each of the 66 mouse cytokines relative to an appropriate 6-point regression standard curve in which the mean fluorescence for each cytokine standard was transformed into known concentrations (pg/mL or ng/mL). For muscle lysates, cytokine concentrations were normalized to total protein before further analysis. The multiplex assays were carried out on three separate occasions, each time with different samples: 1) pre- and post- exercise serum from sprint and endurance mice, 2) pre- and post- exercise serum from voluntary running mice, and 3) all muscle lysates from all 4 exercise regimes. All samples that were used for direct comparison or normalization were run on the same plate.

### **QuantiGene Plex assay (QGP) for measuring cytokine mRNA level**

QuantiGene Plex assays enable simultaneous quantification of up to 80 genes of interest in a single well of a 96-well plate. This method is hybridization-based and incorporates branched DNA (bDNA) technology (44, 45). Because it relies on signal amplification rather than target amplification for direct measurement of RNA transcripts, no RNA isolation and reverse transcription is needed. QuantiGene assay has comparable or better linear range and relative

accuracy when compared to standard real-time PCR method (46). All Gene-specific QuantiGene probes were validated and provided by Thermo Fisher Scientific. Soleus and plantaris muscle fibers harvested from mice were weighed, and placed on dry ice until ready to process. 5-15 mg of tissue was used in sample preparation. Tissues were lysed in 300  $\mu$ L of homogenizing solution (QGP Assay Kit, Thermo Fisher Scientific, Waltham, MA) per 10 mg tissue, using an MP24 fastprep (MP Biomedicals, Santa Ana, CA) with MP lysing matrix A tubes (Cat #6910-100, MP Biomedicals). Tissue homogenates were heated at 65°C for 1 h, with vortexing every 10 min. Heated samples were centrifuged at room temperature for 15 min at 16,000 x g to sediment the matrix, and the supernatant was transferred to clean microcentrifuge tubes. The supernatant was clarified by repeating the above centrifugation step, and the resultant supernatant transferred to another clean microcentrifuge tube. Supernatants were added directly to the QGP hybridization plate following the addition of master mix prepared according to manufacturer's instructions. The hybridization plate was incubated overnight at 57°C with shaking at 600 rpm. The next day, the plate was processed according to manufacturer's instructions, and read on a Luminex 200 instrument (Luminex, Austin, TX). Data was analyzed and fold change calculated according to manufacturer's instructions, using *Hprt* and *Actb* as reference genes. Statistical analyses were performed using a one-way ANOVA with Dunnett's post-test with the sedentary group as the control.

### **Quantitative real-time PCR analysis**

Total RNA was isolated from liver, visceral (epididymal) and subcutaneous (inguinal) white adipose tissues using Trizol® (Life Technologies). Random primers and GoScript reverse transcriptase (Promega) were used to generate cDNA. Quantitative real-time PCR analyses were

performed on CFX Connect Real-Time system (Bio-Rad) using iTaq Universal SYBR Green Supermix (Bio-Rad). The data were normalized to 36B4 (also known as acidic ribosomal phosphoprotein P0 (RPLP0)) to generate a  $\Delta C_t$  value, and then a  $\Delta\Delta C_t$  was obtained by normalizing the data to the mean  $\Delta C_t$  of the control group (47). 36B4 gene was selected for normalization because it had the least variation across tissue samples. All primers used for real-time PCR analyses are listed in **Table 2**.

| Gene                 | Forward primer          | Reverse primer           |

**Table 2. Quantitative real-time PCR primers used in the study**

### Confirmatory experiment with a second cohort of mice

A second independent cohort of endurance and sedentary mice was used to confirm some of the findings obtained from the multiplex assays. As before, 8 week-old C57BL/6J mice were

purchased from Jackson Labs for the experiments with N=10 per group. However, data for the endurance group reflects N=6 because 2 mice refused to run despite being adequately acclimated to the treadmill and 2 mice were running when the treadmill experienced technical issues so had to be taken out of the study. The experiments were conducted exactly as described previously with the exception of timing of the pre-exercise blood draws. Given that a large volume of serum was needed to satisfy the volume requirements for multiple ELISAs, blood was drawn on two separate occasions before the exercise experiment: once 3 weeks before the endurance run and once 2 weeks before the run. Serum from both blood draws was combined before it was assayed. Mice were allowed to recover for two full weeks after the last pre-exercise blood draw as opposed to the one week of recovery with the first cohort. Thus, the mice in this second cohort were approximately 2 weeks older and a few grams heavier than their counterparts in the first cohort on the day of the experiment. Otherwise, all data including time to exhaustion, blood glucose, and blood lactate levels matched very well between the two cohorts. Soleus and plantaris lysates were prepared as described except both muscles were used and the volume of buffer was reduced to 350  $\mu$ L. These changes were implemented to increase the signal in the ELISAs.

The following cytokines were measured via ELISA in the pre- and post- exercise serum from the endurance group and soleus and plantaris lysates from all endurance and sedentary mice: MCP-5, KC, MIP-2, MIP-3, IFN $\gamma$ , and sTNFRI. ELISAs for all targets were purchased from R&D Systems with the exception of sTNFRI, which was purchased from Thermo Scientific. Assays were carried out according to the manufacturer's protocol. Muscle lysates were assayed undiluted, and cytokine concentrations in these samples were first normalized to total protein before further analysis.

## **Data analysis**

For a given analyte, not all samples were successfully detected in the multiplex analysis. Data for a given analyte was analyzed when analyte levels were detected in at least 3 out of the 10 samples. To enable paired t-test analysis (where  $N \geq 3$ ), serum analyte levels must be detected in both pre- and post-exercise samples from the same mouse. It should be noted that the vast majority (~90%) of statistically significant data were obtained from sample size  $N=9-10$ . For statistical analysis, a paired t-test was used to analyze pre-exercise versus post-exercise serum data. The nonparametric Wilcoxon matched pairs test was used to analyze data in which the differences (post minus pre) were not Gaussian. Lysate data were analyzed by 1-way-ANOVA. The means from each exercise condition were compared to that from the sedentary condition using Dunnett's post-test.  $P < 0.05$  was considered significant. All data is reported as mean  $\pm$  SEM. Data was analyzed using Graph Pad Prism 7 software. For each data set, false discovery rate analysis was also performed with GraphPad Prism 7 using the recommended two-stage step-up method of Benjamini, Krieger and Yekutieli. The false discovery rate (Q) was set to 5%.

## **RESULTS**

### **Using multiplex technology to measure cytokine levels**

Three exercise paradigms—sprint, endurance exercise, and voluntary wheel running—representing an acute and chronic forms of physical activity, were used in the present study to assess changes in circulating serum cytokines, as well as their protein levels in glycolytic (plantaris) and oxidative (soleus) muscles. A bead-based multiplex profiling method was used to quantify 66 cytokines in both serum and muscle lysates. We could reliably detect and measure up to 52 cytokines from among the 66 cytokines profiled (**Tables 3 and 4**). This is not surprising

**Table 3**

| Analyte         | Serum cytokine       |                       |                      |                       |                             |                       |

**Table 3. Summary of cytokine protein levels in serum in response to sprint, endurance run, or voluntary wheel running for 1 week.** All values shown as average  $\pm$  S.E. Those cytokines that are below the detection limit of the assay are indicated by "--". N=10 mice per group. \*p< 0.05; \*\*p<0.01; \*\*\*p<0.001.

**Table 4. Summary of cytokine protein levels in soleus and plantaris muscles in response to sprint, endurance run, or voluntary wheel running for 1 week.** All values are normalized to the control sedentary group and shown as fold change  $\pm$  S.E. Those cytokines that are below the detection limit of the assay are indicated by "--". N=10 mice per group. \*p< 0.05; \*\*p<0.01; \*\*\*p<0.001.

given that some cytokines are expressed at very low levels and are only upregulated in the context of immune activation in response to infection. Remarkably, a large fraction of the cytokines

detected were significantly altered by acute and chronic exercise (**Tables 3 and 4**). When adjusted for false discovery, most of the significant changes still remain (**Tables 5-7**). Using a second independent cohort of mice subjected to an endurance run, we confirmed the validity of the multiplex assay using the standard, conventional ELISA method. Of the six chosen targets analysed, three (MCP-5/CCL12, KC/CXCL1, and MIP-2/CXCL2) were significantly different between pre- and post-exercise serum, and the direction of change matched that of the multiplex data (**Fig. 1**). Similarly, three targets were significantly different between sedentary and exercised soleus, and the direction of change matched that of the multiplex data (MCP-5/CCL12, IFN- $\gamma$ , and sTNFRI). In agreement with the multiplex data, none of the targets (except sTNFRI) were significantly different between sedentary and exercised plantaris as measured by ELISA (**Fig. 1**).

### **Changes in serum cytokine levels in response to different exercise regimes**

In serum, we observed significant changes in eight (17%), thirteen (29%), and ten (20%) circulating cytokines in response to a single bout of sprint, endurance run, and 1-week voluntary wheel running, respectively (**Table 3**). A much greater overlap was seen between a single bout of endurance run and voluntary wheel running (**Fig. 2**). With the exception of CXCL1, the direction of change in serum levels was consistent among all the overlapping cytokines in three of the exercise paradigms. While there was overlap, a single bout of sprint and endurance run also altered different sets of cytokines (**Fig. 2**). Of the serum cytokines altered by acute or chronic exercise, 4 were upregulated and 14 were downregulated.

Table 5

Table 7. Un-adjusted and adjusted (false discovery rate; FDR) p-values for cytokines in plantaris muscle

A

B

**Figure 1. Measurements of six cytokines in a second independent cohort of mice subjected to an endurance run using conventional ELISA method.** (A) ELISA quantification of MCP-5/CCL12, MIP-3α/CCL20, KC/CXCL1, MIP-2/CXCL2, IFN-γ, and sTNFRI in pre- and post-exercise serum. (B) ELISA quantification of MCP-5/CCL12, MIP-3α/CCL20, KC/CXCL1, MIP-2/CXCL2, IFN-γ, and sTNFRI in sedentary and exercised soleus and plantaris muscle lysates.

**Figure 2. Venn diagram of cytokines altered by sprint, endurance run, or voluntary wheel running in serum.** Upregulated cytokines are highlighted in red. Downregulated cytokines are highlighted in green. Cytokines that are upregulated in one exercise paradigm but downregulated in another are highlighted in purple.

### Changes in cytokine levels in soleus and plantaris in response to different exercise regimes

In oxidative soleus muscle, an even greater proportion of the detected cytokines was altered by acute and chronic exercise relative to the sedentary control group (**Table 4**). The protein levels of eleven (24%), twenty-one (47%), and twenty-six (62%) cytokines were significantly changed in response to a single bout of sprint, endurance run, and 1-week voluntary wheel running, respectively. Again, we observed a much greater overlap between a single bout of endurance run and 1-week voluntary wheel running (**Fig. 3A**). However, the direction of change (up or downregulated) among the overlapping cytokines was different depending on the types of physical

**Figure 3. Venn diagram of cytokines altered by sprint, endurance run, or voluntary wheel running in soleus and plantaris muscles.** Upregulated cytokines are highlighted in red. Downregulated cytokines are highlighted in green. Cytokines that are upregulated in one exercise paradigm but downregulated in another are highlighted in purple.

activity (**Table 4** and **Fig. 3A**). Despite significant overlap, different types of physical activity clearly altered different sets of cytokines in soleus muscle (**Fig. 3A**). Of the 34 cytokines whose levels changed in soleus muscle by acute or chronic exercise, 11 were upregulated, 11 were downregulated, and 12 were either up or downregulated depending on the types of physical activity.

A very different cytokine profile was seen for the glycolytic (plantaris) muscle when compared to the oxidative (soleus) muscle. Relative to the sedentary control group, the protein levels of four (8%), three (6%), and twenty-two (50%) cytokines were significantly changed in plantaris muscle in response to a single bout of sprint, endurance run, and 1-week voluntary wheel running, respectively (**Table 4**). In striking contrast to the soleus muscle, only 3-4 cytokines were altered by a single bout of sprint or endurance run in the plantaris muscle (**Fig. 3B**). The majority

of the cytokine changes in plantaris were seen in mice subjected to 1-week of voluntary wheel running. Minimal (1-2 cytokines) overlap was observed in plantaris for the three different types of exercise. Of the 25 cytokines altered in plantaris muscle by acute or chronic exercise, 4 were upregulated, 20 were downregulated, and 1 was either up or downregulated depending on the types of physical activity.

### **Overlap of cytokine changes in serum, soleus, and plantaris in response to each type of exercise**

Next, we asked how many of the systemic changes in circulating serum cytokines paralleled the local protein changes in soleus and plantaris. This would help address which among the systemic cytokine changes in blood is directly due to the expression and secretion from skeletal muscle. Surprisingly, for a single bout of sprint, no overlap in cytokine profiles was seen between serum, soleus, and plantaris muscles (**Fig. 4A**). Different sets of cytokines were apparently altered in oxidative (soleus) and glycolytic (plantaris) muscles, with the majority of changes seen in soleus muscle fibers. Combined, a total of 21 cytokines were altered by sprint, with 13 upregulated, 7 downregulated, and 1 with opposite changes between serum and soleus muscle.

For a single bout of endurance run, the majority of the cytokine changes were seen in serum and soleus muscle (**Fig. 4B**). However, no overlap (common to all three) was seen between serum, soleus, and plantaris. Although seven cytokine changes showed overlap between serum and soleus muscle, the direction of change (up or downregulated) was different for three of the cytokines (**Fig. 4B**). Combined, a total of 28 cytokines were altered by a single bout of endurance run, with 13 upregulated, 12 downregulated, and 3 with opposite changes between serum and soleus muscle.

**Figure 4. Venn diagram of cytokines altered by sprint, endurance run, or voluntary wheel running in serum and in soleus and plantaris muscles.** Upregulated cytokines are highlighted in red. Downregulated cytokines are highlighted in green. Cytokines that are upregulated in one tissue exercise paradigm but downregulated in another are highlighted in purple.

Of the three different types of exercise, the greatest number of cytokines changes were seen in the 1-week voluntary wheel running group relative to the sedentary control group (**Fig. 4C**). Large numbers of cytokine changes showed overlap between serum and soleus or plantaris, as well as between oxidative (soleus) and glycolytic (plantaris) fibers. Interestingly, most of the cytokine changes induced by voluntary wheel running were in the “downregulated” direction (**Fig. 4C**; highlighted in green); in contrast, a large fraction of the cytokine changes seen in sprint and endurance run were in the “upregulated” direction (**Fig. 4A and B**; highlighted in red). Combined, a total of 34 cytokines were altered by 1-week voluntary wheel running, with 2 upregulated, 28 downregulated, 4 with opposite changes between different tissues.

### **Changes in cytokine mRNA levels in plantaris and soleus in response to different exercise regimes**

We next examined changes in cytokine mRNA levels in oxidative (soleus) and glycolytic (plantaris) muscles in response to the three different types of exercise. We used the QuantiGene Plex assays to simultaneously measure the mRNA levels of 63 cytokines (**Tables 8 and 9**). With the exception of CXCL9 transcript, we were able to detect the mRNA of 62 cytokines. Relative to the sedentary control group, the mRNA levels of six (10%), eight (13%), and fourteen (22%) cytokines were significantly changed in soleus in response to sprint, endurance run, and voluntary wheel running, respectively. In plantaris muscle, however, the mRNA levels of five (8%), thirteen (21%), and five (8%) cytokines were significantly changed in response to sprint, endurance, and voluntary wheel running, respectively. Surprisingly, most of the mRNA changes in soleus and plantaris show relatively little overlap between the three types of physical activity (**Fig. 5A and B**). In soleus muscle, 10 cytokine mRNA were upregulated, 7 downregulated, and 3 changed in

**Table 8. Summary of cytokine mRNA levels in soleus muscle in response to sprint, endurance run, or voluntary wheel running for 1 week.** All values are normalized to the control sedentary group and shown as fold change  $\pm$  S.E. Those cytokines whose mRNA that are not detected are indicated by "--". N=10 mice per group. \*p< 0.05; \*\*p<0.01; \*\*\*p<0.001.

Those cytokines whose mRNA that are not detected are indicated by "--". N=10 mice per group. \*p< 0.05; \*\*p<0.01; \*\*\*p<0.001.

**Figure 5. Venn diagram of cytokine mRNA altered by sprint, endurance run, or voluntary wheel running in soleus and plantaris muscles.** Upregulated cytokines are highlighted in red. Downregulated cytokines are highlighted in green. Cytokines that are upregulated in one exercise paradigm but downregulated in another are highlighted in purple.

the opposing directions depending on the types of exercise. In plantaris muscle, 5 cytokine mRNA were upregulated, 12 downregulated, and 1 changed in the opposite direction between endurance and chronic wheel running.

### Concordance between changes in cytokine mRNA and protein levels in muscle in response to exercise

Next, we addressed the issue of concordance between changes in cytokine mRNA and protein expression in soleus and plantaris muscles. In oxidative (soleus) muscle, parallel reductions in transcript and protein were observed for IL-15, VEGF, sIL1RI, sVEGFR1, sVEGFR2, and sgp130, whereas parallel increases were only observed for CCL12 and TIMP-1. In glycolytic (plantaris) muscle, parallel reductions in transcript and protein were observed for VEGF and

CCL21, whereas a parallel increase was only observed for TIMP-1. Essentially, the majority of the cytokine changes reported here showed discordance between transcript and protein levels (comparing **Tables 4, 8, and 9**).

### **Expression of cytokines in adipose and liver in response to exercise whose changes in serum were not matched by changes in muscle**

Given that the changes in a subset of serum cytokines were not matched by the corresponding changes in their protein levels in muscle, we addressed whether this could be due to secondary adaptive changes in their expression in non-muscle tissues. Acute and chronic exercise can alter systemic metabolism in response to energetic demands, and we have previously shown that different metabolic states alters circulating cytokine levels (43). Thus, we determined the expression of cytokine transcripts in liver and two major fat depots (visceral and subcutaneous white adipose tissues), major metabolic organs known to produce and secrete a wide array of cytokines and chemokines in response to different physiological stimuli. We focused our analyses only on those cytokines whose altered serum levels were not accounted for by changes in protein levels in skeletal muscle in response to exercise. As shown in **Fig. 6**, depending on the types of exercise, expression of cytokine transcripts could be either up- or down-regulated in the liver and/or adipose tissues. With a couple exceptions, most of these changes in mRNA paralleled the

**Figure 6. Quantitative real-time PCR analysis of select cytokine transcripts in liver and adipose tissues in response to acute and chronic exercise.** Relative mRNA expression of different cytokines in liver, visceral (epididymal) and subcutaneous (inguinal) fat depots. We only focus our analysis on those cytokines whose altered circulating levels were not matched by the corresponding changes in protein levels in skeletal muscle. All mRNA expression values were normalized to 36B4. These values were then normalized to the sedentary condition and the data are shown as average  $\pm$  S.E. All *p*-values were calculated using an unpaired *t*-test with Welch's correction (comparing the exercise condition to the sedentary condition). \* $< 0.05$ ; \*\*  $p < 0.01$ ; \*\*\*  $p < 0.001$ . (**figure on the following page**)

cytokine changes seen in circulation. For example, for a single bout of sprint, increased serum EPO and IL-20 levels were paralleled by increased mRNA expression in visceral white adipose tissue, whereas reduced serum IL-17F, sgp130, and INF- $\gamma$  levels were paralleled by reduction in mRNA expression in either visceral or subcutaneous adipose tissue. For a single bout of endurance run, reduced serum sIL-4R, sTNF-RII, TIMP-1, IL-16, INF- $\gamma$ , and CCL20 levels were paralleled by reduced mRNA expression in liver and/or adipose tissue. For voluntary wheel running, reduction in serum sTNF-RII, TIMP-1, and CCL12 levels were paralleled by reduced mRNA expression in subcutaneous adipose tissue. These results suggest that changes in a subset of circulating cytokines could, at least in part, be accounted for by the corresponding changes in transcript levels in liver and/or adipose tissues.

## DISCUSSION

Here, we undertook an antibody-based profiling approach to determine the extent by which exercise modulates local cytokine levels in glycolytic and oxidative muscle fibers, as well as their systemic circulating levels, in response to three different types of physical activity—an acute sprint and endurance run, or chronic exercise in the form of voluntary wheel running. We chose to focus on cytokine family members as potential myokines given their well-known pleiotropic functions that could potentially link exercise to myriad physiological effects that include immunity (48), inflammation (6), metabolism (43), food intake (32, 49), and autophagy (50).

All the significant changes in cytokine mRNA and protein levels are summarized in **Table 10**. From our antibody-based profiling studies of exercise-regulated cytokines, several notable observations are highlighted. a) Chronic exercise in the form of wheel running consistently induced more cytokine changes than an acute single bout of sprint or endurance run. This is

**Table 10. Summary of all the statistically significant changes in cytokine mRNA and protein levels in response to sprint (S), endurance run (E), and voluntary wheel running (VWR).**

perhaps not surprising as repeated bouts of exercise lead to skeletal muscle adaptation (51). b) Acute and chronic exercise appear to alter distinct sets of cytokines in serum and skeletal muscle, with varying degrees of overlap depending on the type of physical activity. This presumably reflects differences in skeletal muscle adaptation to repeated voluntary wheel running versus a stress-like response to an acute bout of exercise. c) There is more overlap in cytokine profile between a single bout of endurance exercise and chronic wheel running, particularly in serum and oxidative soleus muscle. This suggests that exercise intensity affects the nature of the cytokine response, as endurance and chronic wheel running represent low-intensity exercise whereas an

exhaustive sprint reflects high-intensity exercise. d) We observed more exercise-regulated cytokine changes in skeletal muscle than in serum. This could reflect a higher local concentration of cytokines and hence our greater ability to reliably detect their differences. The circulating plasma levels of most cytokines are in the nanogram and picogram per milliliter range. Due to the dilution effect of plasma, only relatively large changes in cytokine secretion into circulation by skeletal muscle in response to exercise would be detected. Alternatively, some exercise-regulated cytokines act locally within skeletal muscle and are not secreted into circulation. e) Interestingly, between muscle fiber types, we observed significantly more cytokine changes in oxidative soleus compared to glycolytic plantaris muscles irrespective of the types of exercise (sprint, endurance, wheel running). With some exceptions (52), in most human exercise studies, gene and protein expression analyses were performed on quadriceps muscle biopsies consisting of mixed fiber types. As such, cytokine response to exercise in different muscle fiber types in humans is largely unknown. Our study thus highlighted the utility of animal models in addressing questions difficult to answer in human-based exercise studies. f) In oxidative soleus muscle, we observed significant overlaps in cytokine profiles in response to sprint, endurance run, and chronic wheel running. In striking contrast, only minimal overlaps in cytokine profiles were observed in glycolytic plantaris muscle. Thus, not only are more cytokines changed in soleus compared to plantaris, but also those changes seen in soleus show greater overlap between different types of physical activity. These types of unexpected insights relevant to skeletal muscle physiology illustrate the advantage of assessing gene and protein expression in different muscle fiber types. g) In a single bout of exhaustive sprint and endurance run, we observed significantly more cytokines being upregulated than downregulated in serum and in muscle. This may reflect normal physiological stress responses associated with acute exercise. In marked contrast, chronic voluntary wheel running

predominantly resulted in cytokine downregulation in serum and muscle. These differences likely reflect skeletal muscle adaptation to chronic exercise and may be linked to general improvements in inflammatory profiles associated with regular exercise.

IL-6 is the first and most widely studied exercise-regulated cytokine (53). As expected based on previous studies in humans, we observed a significant increase in IL-6 protein level in mouse skeletal muscle in response to a single bout of sprint or endurance exercise (**Table 4**). Interestingly, only oxidative (soleus), but not glycolytic (plantaris), muscle fibers show increased IL-6 protein level in response to sprint or endurance run. One week of voluntary wheel running, however, resulted in reduced IL-6 in both soleus and plantaris, as well as in serum. This reduction presumably reflects skeletal muscle adaptation to repeated bouts of exercise. In healthy humans subjected to 10 weeks of endurance training, contraction-induced IL-6 expression was reduced (54). Intriguingly, neither sprint nor endurance run acutely raised the circulating level of IL-6 in serum (**Table 3**). This could be due to exercise intensity, or insufficient quantities of IL-6 being secreted into systemic circulation to acutely raise its serum level. While most human studies reported increase plasma IL-6 levels after high intensity exercise, some studies did not observe a similar increase in plasma IL-6 after a lower intensity exercise (37). It has been noted that circulating levels of cytokines can vary widely between individuals subjected to different types of exercise (28).

Intriguingly, most of the secreted cytokine receptors (10 out of 13) profiled are altered by exercise. These include sgp130, sRAGE, sIL-1RI, sIL-1RII, sIL-4R, sIL-6R, sTNF-RI, sTNF-RII, sVEGFR1, and sVEGFR2. The soluble form of cytokine receptors in plasma can be generated by multiple mechanisms that include ectodomain shedding by zinc metalloproteinases (e.g., TACE/ADAM17 and ADAM19), as well as by alternative mRNA splicing (42). Protease-

mediated release of receptor ectodomain has been demonstrated for TNF-RI, TNF-RII, IL-1RII, IL-4R, and IL-6R, whereas the soluble forms of gp130, RAGE, VEGFR1, and VEGFR2 are generated by alternative mRNA splicing (42, 55). While previous studies have looked at soluble IL-6R levels in response to exercise in humans (56, 57), our current study represents the first attempt to quantify changes in multiple secreted cytokine receptors in response to exercise. Our results suggest that soluble cytokine receptors could be generated by potentially novel exercise-regulated proteolytic and alternative mRNA splicing mechanisms. In principle, these soluble receptors could influence cytokine signaling by functioning as receptor agonists or antagonists.

Interestingly, there is a subset of 17 circulating cytokines whose changes in serum were not matched by their corresponding changes in muscle. Presumably, these cytokines (EPO, IL-20, IL-17A/F, sgp130, sIL-4R, CCL17, G-CSF, CX3CL1, CXCL1, IL-16, TIMP-1, sTNF-RII, sTNF-RI, IFN- $\gamma$ , CXCL10, CCL20, and CCL12) are produced and secreted by non-muscle tissues. These changes could be attributed to several potential mechanisms that are dependent or independent of contracting skeletal muscle. Primary cytokines, and other potential myokines, that are secreted into circulation by contracting skeletal muscle could convey a signal to other non-muscle tissues to alter the expression and secretion of secondary cytokines. Liver and adipose tissues are also known to produce and secrete a variety of different cytokines. Given the energetics demands of contracting skeletal muscle, indirect metabolic changes in liver and adipose tissue induced by exercise could potentially also alter the expression and secretion of secondary cytokines. In support, we indeed observed parallel changes in cytokine expression in liver and/or adipose tissue in response to exercise that could, at least in part, account for their changes in circulation but not in skeletal muscle. Thus, our data highlighted the primary cytokine response of skeletal muscle

and the secondary cytokine response in non-muscle tissues resulting from potential exercise-mediated tissue crosstalk.

When skeletal muscles isolated from the same mice were subjected to quantitative mRNA analysis, we found only minimal concordance between cytokine mRNA and protein levels, irrespective of exercise regimen. These observations suggest the importance of posttranscriptional regulation of cytokine expression and secretion in contracting skeletal muscle *in vivo*. Some of these posttranscriptional mechanisms could involve exercise-regulated stabilization of cytokine mRNA transcripts and/or microRNA (miRNA) mediated regulation of mRNA translation (28). Given that posttranscriptional control of cytokine/myokine expression in response to exercise is largely unexplored, our data provided a basis and impetus to further explore these underappreciated mechanisms in the context of physical activity.

Of the 66 cytokines profiled, a surprisingly large fraction is altered by acute and/or short-term exercise. Most of these altered cytokines are shown for the first time to be regulated by exercise *in vivo*. In recent studies, Scheler et al. profiled 23 different cytokines in cultured human myotubes using similar bead-based multiplex approach and showed that 11 cytokines are regulated by electrical pulse stimulation (27); these include IL-8, CXCL1, IL-6, LIF, IL-4, IL-13, IL17A, IL-1 $\beta$ , G-CSF, TNF, and CCL2. Raschke et al. used an antibody array to profile 179 peptides (covering different classes of secretory proteins in addition to cytokines), and identified 23 novel exercise regulated cytokines in electrical pulse stimulated human myotubes (26); these include IL-1 $\alpha$ , IL-3, IL-10, IL-16, IL-22, IL-28A, IL-29, IL-31, IFN- $\gamma$ , TPO, RAGE, CCL1, CCL4, CCL15, CCL17, CCL18, CCL21, CCL23, CCL24, CCL26, CXCL6, CXCL9, and CXCL13. Of the known exercise-regulated cytokines reported in cultured human myotubes (26, 27), we were able to confirm the majority of them *in vivo*, in particular those cytokines that were included in our

multiplex assay. This suggests that many of the cytokine responses we observed are most likely due to changes in the expression and secretion of cytokines from skeletal myotubes. Our results validate the use of rodent exercise models to study cytokine/myokine response in humans. Excluding these recently described exercise-regulated cytokines in cultured human myotubes, our *in vivo* mouse studies—involving three different exercise regimens and two different muscle fiber types—identified an additional 22 novel exercise-regulated cytokines/myokines not previously reported. These include IL-9, IL-12 (p40), IL-20, IL-33, M-CSF, CXCL10, CXCL2, CCL5, CCL3, CCL12, CCL19, CCL20, EPO, TIMP-1, sgp130, sIL-1RI, sIL-1RII, sIL-6R, sTNF-RI, sTNF-RII, sVEGFR1, and sVEGFR2. Of these novel exercise-regulated myokines, a subset (IL-20, CXCL2, CXCL10, CCL12, CCL20, sTNF-RI, sTNF-RII, and TIMP) can be considered “exercise factors” based on the definition that they are produced by skeletal muscle in response to exercise and are secreted into the circulation (11).

Most of the exercise-regulated cytokines we uncovered play myriad roles in the immune and non-immune systems. Many cytokine functions are physiological context-dependent and their effects are cell-type specific (38); their excessive production or suppression are often causally linked to disease. In the context of exercise, the levels of a surprisingly large number of cytokines are changed either locally within skeletal muscle or systemically. It appears that both the pro- and anti-inflammatory cytokines are altered by acute and chronic exercise in rodents (**Table 10**) and in humans (58). It has been suggested that the beneficial local and systemic effects of chronic exercise are due to exercise-induced hormesis, whereby a low level of stress upregulates existing cellular and molecular pathways that improve whole-body physiology (e.g., metabolism and immunity) (58, 59). Thus, it may be a specific combination of cytokines (with diverse and opposing functions) whose direction, magnitude, and duration of change underlie exercise-induced

hormesis. In this context, it is worth noting that chronic exercise with running wheel induced more cytokine changes than either an acute low-intensity (endurance) or high-intensity (sprint) exercise. While this is beyond the scope of the present study, future investigations using genetic gain- or loss-of-function mouse models of select cytokines are clearly needed to further pinpoint the biological effects of muscle-derived cytokines/myokines in muscle and non-muscle tissues.

Several limitations and caveats are noted in the present studies. First, we did not analyze all the known cytokines discovered to date. This is limited by cost and the availability of cytokine-specific multiplex reagents. Second, we did not use an *in vitro* exercise model (e.g., EPS-stimulated myotubes) to directly show that the cytokine changes we see in soleus and plantaris muscle fibers are indeed derived from skeletal myotubes and not from other potential cell types such as satellite cells, endothelial cells, fibroblastic cells, and resident immune cells. It is known that eccentric or resistance exercise, or prolonged running (e.g., marathon), in humans result in muscle damage, leading to the influx of inflammatory leukocytes that can be the source of cytokines upregulated in muscle [extensively reviewed in (60)]. While we cannot rule out this possibility, the type and duration of exercise the mice were subjected to in our study generally do not cause significant muscle damage. Indeed, when obese mice were subjected to endurance interval training, significantly less inflammation and macrophage infiltration were observed in skeletal muscle (61). Since our *in vivo* study confirmed a majority of the exercise-regulated cytokines in cultured human myotubes (26, 27), we presume the novel exercise-regulated cytokines found in the present study are likely to be derived from myotubes. Third, we only measured transcript, and not protein, levels of a select set of cytokines in liver and adipose tissues. Thus, whether changes in mRNA translate into changes in protein levels remain to be determined. Fourth, we did not directly demonstrate the release of cytokines from exercised muscle into

circulation. While this may be technically challenging to perform in mice, *in situ* cytokine flux analysis will provide further insights into how different muscle fiber types modulate the production and secretion of cytokines in response to different exercise. Fifth, although mice run only during the dark cycle (62), one potential caveat of the voluntary exercise group was that the mice had access to the running wheel until the morning before they were sacrificed. However, when we examined the cytokine profiles, the number and type of cytokine changes were significantly different between acute (sprint and endurance run) and chronic (wheel running) exercise groups despite some overlaps (**Fig. 2 and 3**), suggesting that we could discriminate between the two exercise effects. Sixth, the pre-exercise values of some cytokines in the voluntary wheel running group were significantly higher than the pre-exercise values for the sprint and endurance groups. The reason for this is unknown. While all mice were handled identically, the serum samples from the wheel running group were not analyzed at the same time as the sprint and endurance groups. However, samples that were directly compared to one another or used for normalization were always analyzed on the same plate; specifically, serum samples from the pre- and post- sprint and endurance groups were run together while the samples from the pre- and post- wheel running were run together. Our analyses focused on the changes in cytokine levels in each pre- and post-exercise condition. We do not directly compare serum data between exercise regimens. Thus, the differences in absolute values between exercise conditions should not affect the interpretation of our data. Despite these limitations, our current studies reveal important insights concerning exercise regulation of local and systemic cytokine levels.

In summary, our current cytokine profiling study in mice, along with other published studies on exercise-regulated myokines in humans and animal models, indicate that physical activity can significantly alter the skeletal muscle secretome. Many myokines/cytokines have

pleiotropic functions, and some may have opposite effects depending on biological and physiological contexts. Given this complexity, we speculate that a right combination, magnitude, and direction of myokine changes induced by regular exercise, rather than one or two dominant secretory proteins, are likely responsible for the multi-organ effects and health benefits of exercise. The inherent systems-level response to physical activity may pose a major challenge to produce an “exercise pill” that can mimic and recapitulate all the local and systemic physiological and adaptive processes induced and suppressed by regular exercise.

Little, H. C., Rodriguez, S., Lei, X., Tan, S. Y., Stewart, A. N., Sahagun, A., Sarver, D. C., and Wong, G. W. (2019) Myonectin deletion promotes adipose fat storage and reduces liver steatosis. *FASEB J.* [Epub ahead of print]

## ABSTRACT

We recently described myonectin (also known as CTRP15 and erythroferrone) as a novel skeletal muscle-derived myokine with metabolic functions. Here, we use a genetic mouse model to determine myonectin's requirement for metabolic homeostasis. Female myonectin-deficient mice had larger gonadal fat pad, developed mild insulin resistance when fed a high-fat diet and had reduced food intake following a fast, but were otherwise indistinguishable from wild-type littermates. Male mice lacking myonectin, however, had reduced physical activity when fed *ad-libitum* and in the postprandial state, but not during a fast. When stressed with a high-fat diet, myonectin knockout male mice had significantly elevated very-low-density lipoprotein (VLDL)-triglyceride and strikingly impaired lipid clearance from circulation following an oral lipid load. Fat distribution between adipose and liver was also altered in myonectin-deficient male mice fed a high-fat diet. Greater fat storage resulted in significantly enlarged adipocytes and was associated with increased postprandial lipoprotein lipase activity in adipose tissue. Parallel to this was a striking reduction in liver steatosis due to significantly reduced triglyceride accumulation. Liver metabolite profiling revealed additional significant changes in bile acids and one-carbon metabolism pathways. Combined, our data affirm the physiological importance of myonectin in regulating local and systemic lipid metabolism.

## INTRODUCTION

Skeletal muscle takes up the majority of circulating postprandial glucose and plays a vital role in maintaining whole-body energy balance (1, 2). Impaired insulin responsiveness in skeletal muscle is mechanistically linked to type 2 diabetes (3, 4). As a major metabolic organ, skeletal muscle is believed to communicate with other organs and tissues via secreted hormones to

influence whole-body metabolism. The discovery that skeletal muscle dynamically secretes a variety of myokines—proteins that stimulate muscle and non-muscle tissues to regulate various biological processes—has provided a novel and critical conceptual framework to understand skeletal muscle’s role in coordinating integrated physiology (5, 6).

Of the hundreds of proteins secreted by skeletal muscle (7-9), only a few have been functionally characterized; these include myostatin (10-12), IL-6 (13), fibroblast growth factor 21 (FGF21) (14, 15), insulin-like 6 (INSL6) (16), follistatin-like 1 (FSTL1) (17), leukemia inhibitory factor (LIF) (18), IL-7 (19), IL-15 (20), musclin (21, 22), and irisin (23). These myokines either act locally within skeletal muscle as autocrine/paracrine factors or circulate in blood as endocrine factors, linking skeletal muscle to the regulation of physiological processes in non-muscle tissues (6, 11, 13, 14, 23-27).

We recently described myonectin/CTRP15 as a novel myokine expressed predominantly by skeletal muscle (28) and determined that exercise can upregulate its expression and circulating level (28, 29). Myonectin is a member of the C1q/TNF-related proteins (CTRPs) with a signature C-terminal globular C1q domain (28, 30-35). Since our initial identification and characterizations of myonectin (28, 36) it has also been referred to as erythroferrone, a secreted protein induced in erythroblasts that links stress erythropoiesis to iron mobilization in liver in response to blood loss (37, 38).

Using genetic gain- or loss-of-function mouse models, we and others provided *in vivo* evidence for the important metabolic and cardiovascular functions of several CTRP family members (29, 33, 39-59). Unlike other family members, myonectin is the only CTRP whose basal expression is primarily restricted to skeletal muscle. Several lines of evidence suggest that myonectin is a physiologically relevant metabolic regulator (28, 36). First, overnight fasting

reduces and re-feeding increases myonectin mRNA and serum levels. Second, and similar to re-feeding, a bolus of glucose or emulsified lipid administered to overnight-fasted mice increases circulating myonectin (28). The addition of glucose, amino acids, or free fatty acids to cultured myotubes also upregulates myonectin expression, suggesting that nutrient uptake and metabolism by muscle cells is sufficient to induce production of this protein. Third, the expression and circulating levels of myonectin are significantly reduced in diet-induced obese and insulin-resistant mice (28). Fourth, infusion of recombinant myonectin into mice reduces circulating free fatty acid levels by promoting free fatty acid uptake (28). Fifth, myonectin suppresses liver autophagy (36), an intracellular recycling pathway activated in the fasted state and inhibited in the fed state. Finally, circulating level of myonectin is associated with insulin resistance and type 2 diabetes in humans (60, 61). The caveat of our previous functional studies, however, is the reliance on recombinant protein infusion in mice and the use of established muscle and adipocyte cell lines (28, 36); it is unclear whether myonectin/erythroferrone is required for metabolic homeostasis in a physiological context (62). Therefore, we aimed to determine the physiological function of myonectin using a genetic loss-of-function mouse model. Our data provide evidence that myonectin does indeed have a role in regulating lipid metabolism in the context of metabolic stress induced by high-fat feeding, and that this effect is sex-dependent.

## **MATERIALS AND METHODS**

### **Animals**

*Myonectin* (*Erfe/Fam132b*<sup>+/-</sup>) heterozygous mice were obtained from the Mutant Mouse Regional Resource Center (MMRRC) at UC Davis (strain B6;129S5-*Fam132b*<sup>tm1Lex</sup>/Mmucd, ID MMRRC:032289-UCD). Mice were generated by Lexicon Pharmaceuticals (63). We maintained

the mice on the C57BL/6N genetic background for >6 generations. PCR genotyping strategy was provided by MMRRC. Genotyping primers for the myonectin wildtype (WT) allele were: forward, 5'-GTCAGCCTTACCTGCCCAG-3'; and reverse, 5'-GACGTGAATCTC AGTCTGGC-3'; yielding a WT PCR product of 216 bp. Primers for the KO allele were: forward, 5'-GCAGCG CATCGCCTTCTATC-3'; and reverse, 5'-GACCGTCACTGAGGTTCCAC-3'; yielding a KO PCR product of 390 bp. To confirm loss of *myonectin* mRNA from KO mice, quantitative PCR was performed on muscle samples using two independent sets of myonectin-specific primers: Primer set # 1, forward, 5'-TGCTTGGATGCTGTT CGTCAA-3' and reverse, 5'-CAGATGGGATAAAGGGGCCTG-3'; primer set # 2, forward, 5'-GCGAGAGA GCCATCTGGAGCACTG-3' and reverse, 5'-GGTCCCTTTCTTGGCTGCTCGGTG-3'. All mice were housed in polycarbonate cages with *ad-libitum* access to water and food in a temperature-controlled room with 12-hour (h) light–dark cycles. Mice were fed either a high-fat diet (HFD, 60% calories from fat, Research Diets, D12492) or a matched control low-fat diet (LFD, 10% calories from fat, Research Diets, D12450B) throughout the study beginning at 5-6 weeks of age. Body weights of WT and myonectin-KO mice were measured weekly. At the end of the study, mice were euthanized 2 h after food removal in the morning or after an overnight fast followed by 2 h of *ad-libitum* re-feeding. Tissues were dissected, weighed, and snap-frozen in liquid nitrogen for RNA and protein extraction or prepared for histology. Additional tissues were stored at –80°C. All animal experiments were approved by the Animal Care and Use Committee of the Johns Hopkins University School of Medicine.

### **Mouse body composition analysis**

Body composition of myonectin-KO mice and WT littermates was determined using a quantitative nuclear magnetic resonance (NMR) instrument (Echo-MRI-100, Echo Medical Systems LLC, Waco, TX) at the Johns Hopkins University School of Medicine mouse phenotyping core facility. Echo-magnetic resonance imaging analyses measured total fat mass, lean mass, and water content.

### **Indirect calorimetry**

Indirect calorimetry was performed as previously described (54). In brief, WT and myonectin-KO mice were used for simultaneous assessments of daily body weight change, food intake (corrected for spillage), physical activity, and whole-body metabolic profile in an open-flow indirect calorimeter (CLAMS, Columbus Instruments, Columbus, OH). Data were collected for three to four consecutive days to confirm that mice were acclimated to calorimetry chambers (indicated by stable body weights, food intakes, and diurnal metabolic patterns), and data from the following day(s) were analyzed. Rates of oxygen consumption ( $\text{VO}_2$ ) and carbon dioxide production ( $\text{VCO}_2$ ) in each chamber were measured throughout the studies. Respiratory exchange ratio (RER,  $\text{VCO}_2/\text{VO}_2$ ) was calculated by CLAMS software (version 4.02) to estimate relative oxidation of carbohydrates (RER = 1.0) versus fats (RER = 0.7), not accounting for protein oxidation. Energy expenditure (EE) was calculated as  $\text{EE} = \text{VO}_2 \times [3.815 + (1.232 \times \text{RER})]$ .  $\text{VO}_2$ ,  $\text{VCO}_2$ , and EE data were normalized to lean mass. Physical activity was measured by infrared beam breaks in the metabolic chamber. Average metabolic values were calculated per subject and averaged across subjects for statistical analysis.

### **Mouse serum and blood chemistry analysis**

Blood samples were collected by tail bleeds using capillary blood collection tubes (Microvette CB 300; Sarstedt, Newton, NC). Blood samples were allowed to clot on ice then centrifuged for 10 min at 10,000 x g to collect serum. Serum TG and cholesterol levels were measured using an Infinity kit (Thermo Fisher Scientific, Middletown, VA). Non-esterified free fatty acids were measured using a NEFA-HR (2) kit (Wako Chemicals, Richmond, VA).  $\beta$ -hydroxybutyrate was measured using a LiquiColor assay (Stanbio). Assays were performed according to the manufacturer's protocol.

## **ELISA**

Insulin (Millipore), ANGPTL3 (Thermo) and ANGPTL4 (Aviva Systems Biology) levels were measured in serum according to the manufacturer's protocol.

## **Glucose and insulin tolerance tests**

For glucose tolerance tests (GTTs), mice were fasted overnight (~15 h) and subsequently intraperitoneally injected or orally gavaged with a glucose solution in saline at a dose of 1 g glucose/kg body weight. Blood was collected from the tail vein into capillary blood collection tubes before injection and 15 minutes (min) post-injection for assessment of insulin levels. Serum was isolated from blood and stored at -80°C until analysis. Tail vein blood glucose levels at the indicated time points were monitored with a glucometer (NovaMax Plus, Billerica, MA). For insulin tolerance tests (ITTs), mice were intraperitoneally injected with recombinant human insulin (Gibco) diluted in saline after a 2-h fast at a dose of 1-1.5 units insulin/kg body weight. Food was removed between 9:00 AM and 10:00 AM. Tail vein blood glucose was monitored with a glucometer at the indicated time points.

### **Lipid tolerance test**

After an overnight fast (~15 h), mice were orally gavaged with 20% emulsified intralipid (soybean oil, Sigma) at a dose of 10  $\mu$ L/g body weight. Blood was collected from the tail vein into capillary blood collection tubes before gavage and 1, 2, 3, and 4 h post-gavage. Serum was isolated from blood samples and assayed for triglyceride (TG) and non-esterified fatty acids (NEFA) using commercially available kits according to the manufacturer's protocol.

### **Hepatic VLDL-TG secretion**

Mice were fasted for 4 h, beginning 2 h into the light cycle. Poloxamer 407 diluted in saline was intraperitoneally injected at a dose of 1 mg/g body weight to inhibit LPL activity. Blood was collected from the tail vein into capillary blood collection tubes before injection and at 1, 2, 4, and 8 h post-injection. Serum was isolated from blood and assayed for TG using a colorimetric kit.

### **Intestinal lipid absorption and secretion**

Overnight fasted mice (~15 h) were intraperitoneally injected with poloxamer 407 diluted in saline at a dose of 1 mg/g body weight to inhibit LPL activity. After 1 h, mice were orally gavaged with 20% emulsified intralipid (10  $\mu$ L/g body weight). Blood was collected from the tail vein into capillary blood collection tubes before gavage and at 1, 2, 3, and 4 h post-gavage. Serum was isolated from blood samples and assayed for TG using a colorimetric kit.

### **Blood and tissue collection**

Mice were anesthetized with isoflurane and blood was collected from the retro-orbital plexus through heparin-coated capillary tubes (Fisher). Blood samples were allowed to clot on ice then centrifuged for 10 min at 10,000 x g. Separated serum was aliquoted and stored at -80°C. Organs were excised and weighed, then flash frozen in liquid nitrogen before being stored at -80°C.

### **Complete blood count analysis**

A complete blood count on blood samples was performed at the Pathology Phenotyping Core at the Johns Hopkins University School of Medicine. Blood samples were collected from the femoral vein using EDTA-coated blood collection tubes (Sarstedt) and analyzed using Procyte Dx analyzer (IDEXX laboratories).

### **Serum lipoprotein analysis**

Lipoprotein analyses were performed at the Metabolism core at the Baylor College of Medicine. 300 µL of serum were pooled from 10 mice of each genotype (30 µL per mouse). Pooled serum samples from WT and KO mice were subjected to fractionation using fast protein liquid chromatography (FPLC), followed by quantification of TG and cholesterol levels in each fraction.

### **Heparin releasable LPL activity in serum**

Mice were fasted overnight (~13 h) and given free access to food for 2 h. The experiment was conducted as previously described (64). Mice were briefly anesthetized with isoflurane and retro-orbitally injected with heparin sodium salt (Sigma) diluted in saline at a dose of 300 U/kg body weight. Blood was collected from the tail vein into capillary blood collection tubes before

injection and 5 min post-injection. Serum was isolated from blood samples. Pre-heparin serum was used to measure serum TG levels. Total lipase activity was measured using a commercial kit (BioVision) in post-heparin serum.

### **Mouse histology**

Adipose and liver tissues from littermate-matched WT and myonectin-KO mice were fixed in 10% formalin at 4°C overnight. Fixed tissues were embedded in paraffin, sectioned, and stained with hematoxylin and eosin (H&E) at the Histology Reference Laboratory at the Johns Hopkins University School of Medicine.

### **Adipocyte cell size analysis**

Adipocyte size was measured using the “MRI Adipocyte Tools” macro in the ImageJ software. All cells in one field of view at 100X magnification per tissue section per mouse were analyzed from a total of 5 WT and 5 KO littermate-matched mice for visceral (gonadal) white adipose tissue and 4 WT and 5 KO littermate-matched mice for subcutaneous (inguinal) white adipose tissue. On average, 230 cells were measured for each sample.

### **Extraction and quantification of mouse hepatic lipid contents**

50-80 mg of frozen liver tissue was homogenized in 500  $\mu$ L ultra-pure water. 200  $\mu$ L lysate were transferred to a new tube and 1 mL of 2:1 chloroform:methanol was added. After thorough mixing, samples were spun at 1,700 rpm for 5 min at 4°C. The lower chloroform phase was transferred to a new tube and dried in a speed vacuum. Extracted lipids were resuspended in 5% Triton x100 in saline. Samples were assayed for TG and cholesterol using commercially available

colorimetric kits (Thermo Scientific). Protein content was measured in the original water lysate using BCA assay (Thermo), and lipid levels were normalized to total protein.

### **Western blotting**

Frozen tissue samples were homogenized in RIPA buffer (50 mM Tris-HCl, pH 7.4; 150 mM NaCl; 1 mM EDTA; 1% Triton X-100; 0.25% deoxycholate) supplemented with a protease inhibitor cocktail (Sigma) and a phosphatase inhibitor cocktail (Roche). Protein content was measured using BCA assay. Samples for Western blotting were diluted in SDS loading dye (final concentration: 50 mM Tris-HCl, pH 7.4, 2% SDS, 6% glycerol, 1% 2-mercaptoethanol, and 0.01% bromophenol blue) and denatured at 95°C for 10 min. 10-20 µg total protein were loaded into each lane of a 10% polyacrylamide gel (BioRad) and separated by electrophoresis. The BioRad Trans-Blot Turbo semi-dry system was used to transfer protein onto PVDF membranes. Blots were blocked in 5% non-fat milk in PBST then exposed to primary antibodies overnight at 4°C. After washing, blots were exposed to secondary antibodies conjugated to HRP for 1 h then developed in ECL (Amersham ECL select). Bands were visualized with MultiImage III FluorChem Q (Alpha Innotech) and quantified using Alphaview Software (Alpha Innotech). All primary antibodies were diluted 1:1000 in PBST + 0.02% sodium azide and all secondary antibodies were diluted 1:5,000 in 5% non-fat milk in PBST. Antibodies used: LPL (GeneTex, GTX101125), Hsc70 (Santa Cruz, sc-7298), perilipin 2 (Thermo, PA1-16972), mouse IgG-HRP (Cell Signaling, 7076), and rabbit IgG-HRP (Cell Signaling, 7074).

### **Liver metabolomics analysis**

Metabolite quantifications of WT (n=10) and myonectin-KO (n=10) liver samples were performed by Metabolon (Morrisville, NC) using their metabolomics platform. Sample processing, compound identification by tandem mass spectrometry, metabolite quantification and data normalization, data extraction, and curation were all performed according to the standard protocol of Metabolon.

### **Stimulated adipose tissue lipolysis**

Mice were fasted for 5 h beginning at 9:30 AM. The  $\beta_3$ -adrenergic receptor agonist, CL 316-243 (Santa Cruz), was diluted in saline and intraperitoneally injected at a dose of 1 mg/kg body weight. Blood was collected from the tail vein into capillary blood collection tubes before injection and at 15 min post-injection. Blood glucose was monitored with a glucometer before and at 15 min after CL 316-243 injection. Serum was separated from blood and assayed for NEFA and glycerol using calorimetric kits (Wako and Sigma, respectively).

### **Tissue LPL activity**

Tissue LPL activity was measured as previously described (65). Briefly, frozen tissue samples were pulverized in liquid nitrogen using a mortar and pestle. Approximately 50 mg pulverized tissue were incubated in Krebs-Ringer solution containing BSA and heparin. After clarifying, the supernatant was used to measure LPL activity using a commercial kit (Roar Biomedical). Activity was normalized to tissue weight.

### **Quantitative real-time PCR analysis**

RNA was isolated from tissues using TRIzol reagent (Invitrogen) according to the manufacturer's protocol and treated with DNase I (New England Biolabs) to remove genomic DNA. For each sample, 1-2 µg total RNA were reverse transcribed using random primers and the GoScript reverse transcription system from Promega. Quantitative real-time PCR was performed on a CFX connect system using iTaq Universal SYBR Green PCR master mix (BioRad). Gene expression was first normalized to *36b4* [also known as acidic ribosomal phosphoprotein P0 (*Rplp0*)] to generate a  $\Delta C_t$  value, and then  $\Delta\Delta C_t$  was obtained by normalizing data to mean  $\Delta C_t$  of the control group (66). Primers used are listed in **Table 1**.

### **Maximal exercise capacity**

Maximal sprint and endurance exercise tests were performed as we described previously (67). Briefly, 12-week-old mice fed a standard chow diet were first subjected to the endurance exercise test. Mice were acclimated to the treadmill for three days before the experiment and the exercise test was carried out on the fourth day. Blood glucose and lactate values were measured before and after exercise using glucose and lactate meters (Nova Biomedical). Blood was collected from the tail vein into capillary blood collection tubes before and after exercise, and silver nitrate sticks were used to cauterize the wound. Mice were run in multiple groups beginning at 9:30 AM until exhaustion. After 2.5 weeks of recovery, mice were subjected to the sprint exercise test. A day before the experiment, mice were re-acclimated to the treadmill using the same protocol as the original day-3 acclimation. For the sprint exercise experiment, mice were run in multiple groups beginning at 8:30 AM until exhaustion. As with the endurance test, blood, glucose, and lactate were collected before and after exercise. The experimenter was blinded with respect to genotype during all exercise tests.

**Table 1**

| Gene                                 | Alias          | Forward primer (5' to 3') | Reverse primer (5' to 3') |

**Table 1. Primers used for quantitative real-time PCR analyses****Recovery after endurance exercise**

Mice used in this experiment were fed a standard chow diet. Mice were acclimated to the treadmill as previously described, but with the addition of a fourth acclimation day in which mice ran on the treadmill at 14 m/min for 5 min at a 10° incline (67). The endurance exercise run was performed on the fifth day when the mice were 11 weeks of age. Mice were fasted for 2 h in the morning before exercise. The run was conducted as previously described (68): 60 min at a speed of 14 m/min at a 10° incline. A shock grid at the back of the treadmill encouraged mice to continue running by administering a mild shock each time they stepped off the belt. If any mice met the pre-determined criteria for exhaustion before the end of the run, they were removed from the treadmill and their data were omitted from analysis (67). The experimenter was blinded with respect to genotype during the treadmill run. Blood glucose and lactate values were measured at the indicated time points using glucose and lactate meters (Nova Biomedical). One cohort of mice received a

glucose gavage within 5 min of the end of the run (0.5 mg glucose/g body weight dissolved in saline). All mice were allowed to recover in their cages with free access to water but no food. After 2 h of recovery following the end of the run, mice were euthanized. Blood and tissues were collected as described above.

### **Tissue glycogen measurement**

Tissue glycogen was measured using a protocol adapted from the NIH-funded Mouse Metabolic Phenotyping Centers (<https://mmpc.org/shared/protocols.aspx>). Frozen whole liver and gastrocnemius muscle were pulverized in liquid nitrogen. Approximately 25 mg liver tissue or 50 mg muscle were homogenized in 400  $\mu$ L 0.9 N perchloric acid. Samples were clarified by centrifuging at 10,000 x g for 10 min at 4°C and transferring the supernatant to a new tube. 50  $\mu$ L supernatant were transferred to each of two reaction tubes, along with 25  $\mu$ L 1M potassium bicarbonate and 125  $\mu$ L 0.4 M sodium acetate buffer (pH 4.8) with or without 5 mg/mL amyloglucosidase (Sigma). Reactions were incubated for 2 h at 40°C on a heat block. After 2 h, reactions were neutralized with NaOH then vortexed and centrifuged for 3 min at 10,000 x g at room temperature. Twenty  $\mu$ L of supernatant from each reaction was used to measure glucose using an Amplex Red glucose assay kit (Invitrogen) according to the manufacturer's protocol. Amyloglucosidase hydrolyzes glycogen into free glucose monomers. For each tissue sample, the amount of glucose in the condition without amyloglucosidase (measuring free glucose) was subtracted from the amount of glucose in the condition with amyloglucosidase (measuring free glucose + glucose from glycogen) to yield the amount of glucose from glycogen only. This value was then normalized to tissue weight.

## Statistical analysis

Comparisons between two groups of data were performed using two-tailed Student's t-tests with Welch's correction and 95% confidence intervals. For experiments with two independent variables, a 2-way ANOVA was conducted and the Bonferroni method was used for multiple comparisons. Graphpad Prism 7 software was used to conduct analyses. Values were considered significant at  $P < 0.05$ . All data are presented as mean  $\pm$  SEM. \*  $P < 0.05$ , \*\*  $P < 0.01$ , \*\*\*  $P < 0.001$ .

## RESULTS

### Myonectin-deficient mouse model

We used a whole-body knockout (KO) mouse model to assess the metabolic function of myonectin *in vivo*. To create a myonectin-null allele, exons 2 through 7 of the myonectin gene were replaced with a neomycin cassette (**Fig. 1A**). Using one set of primers that targeted the WT myonectin gene and another set that targeted the neomycin cassette, we could distinguish between WT, heterozygous, and homozygous null mice (**Fig. 1B**). To verify that myonectin was not expressed in the KO mice, we measured myonectin mRNA levels in the skeletal muscle—the tissue with the highest expression in WT mice (28)—by quantitative PCR. Using two independent primer sets, we confirmed the absence of myonectin transcript (**Fig. 1C**). In the absence of a reliable antibody that can recognize endogenous myonectin without cross-reactivity, we did not quantify myonectin protein level in WT and KO mice. Myonectin KO mice were viable, fertile, born at the expected Mendelian ratio, and exhibited no gross developmental abnormalities.

**Figure 1. Myonectin-deficient mouse model.** (A) Schematic of the gene targeting strategy used to generate myonectin-knockout (KO) mice. The majority of the myonectin gene (exons 2-7) was replaced with a neomycin resistance gene and lacZ reporter cassette. SA, splice acceptor; pA, polyadenylation signal. (B) PCR genotyping showing successful production of wildtype (+/+), heterozygous (Het; +/-), and homozygous KO (-/-) mice. (C) The absence of myonectin transcript in the mouse gastrocnemius muscle was confirmed by quantitative PCR using two independent primer pairs. Primer set #1 targets exon 2 and 3, yielding a PCR product size of 143 bp. Primer set #2 targets exon 4 and 6, yielding a PCR product size of 381 bp. WT n=6 and KO n=6 female mice.

## Myonectin is not required for the physiological response to exercise

Under basal conditions, myonectin is primarily produced in skeletal muscle and its expression can be further induced by exercise (28, 29). We therefore first tested whether it is

required for the physiological response to exercise. During both maximal sprint and endurance exercise on a treadmill, loss of myonectin had no impact on total running distance and the post-exercise serum levels of glucose, lactate, non-esterified free fatty acids, triglyceride, and ketone ( $\beta$ -hydroxybutyrate) levels in female WT and KO mice (**Table 2**). However, we did observe significantly higher pre-exercise serum ketones ( $\beta$ -hydroxybutyrate) in KO female mice relative to WT littermate controls. For male mice, with the exception of post-sprint exercise serum triglyceride levels that were significantly lower in the KO animals, no significant genotypic differences were noted in exercise parameters (**Table 2**). In the post-exercise recovery phase (with or without glucose gavage post-exercise), myonectin deficiency did not significantly affect the ability of KO animals to replenish their skeletal muscle or liver glycogen stores (**Table 3**). These results indicate that myonectin is not required for physiologic response and adaptation to an acute bout of exercise.

### **Myonectin knockout mice fed a control low-fat diet show no overt metabolic phenotypes**

Given its potential role as a postprandial metabolic regulator (28, 36), we tested whether myonectin is necessary for metabolic homeostasis under basal conditions. Male and female WT and KO mice were fed a control low-fat diet (LFD) for 12 weeks, beginning at 6 weeks of age. Neither sex displayed genotypic differences in body weight over time or in body composition (**Fig. 2A-B**). Organ weights (heart, kidney, spleen, liver, and adipose tissue) were also not different between genotypes of either sex (**Table 4**). Indirect calorimetry revealed no differences in *ad-libitum* food intake, metabolic rate, or energy expenditure between WT and KO mice of either sex (**Tables 5 and 6**). However, *ad-libitum* fed female KO mice had a higher respiratory exchange ratio (RER) in the dark cycle and lower physical activity in the light cycle.

**Table 3.** Chow-fed Male and female WT and myonectin-KO mice (at 11 weeks of age) were subjected to an endurance run on the treadmill, and blood glucose and lactate values were measured at the indicated timepoints. Half of the mice received a glucose gavage immediately after completing the run. All mice were allowed to recover for 2 h before euthanization.

Similar to the female KO mice, *ad-libitum* fed male KO mice also had significantly lower physical activity in the light cycle and over a 24-hr period. Myonectin is robustly induced upon re-feeding following a fast (36). We therefore challenged the WT and KO mice with a 24-h fast followed by 24-h free access to food while they were in the metabolic cages. No genotypic differences in either sex were observed during the fast (**Tables 5 and 6**). However, in the refeeding phase, female KO

**Figure 2. No overt metabolic phenotypes were observed in myonectin-KO mice fed a control low-fat diet.** (A) Body weights of female (WT, n=6; KO, n=8) and male (WT, n=6; KO, n=8) mice over time. Mice were weaned at 3.5 weeks of age onto a standard chow diet. At 6 weeks of age, the diet was switched to a control low-fat diet (Research Diets). (B) Body composition analysis of female (WT, n=6; KO, n=8) and male (WT, n=6; KO, n=8) mice at 29 weeks of age. (C-D) Blood glucose levels during glucose tolerance tests (GTT) in female (WT, n=12; KO, n=13) and male (WT, n=12; KO, n=17) mice at 18 weeks of age. (E) Serum insulin levels in male mice at 0 min before glucose injection (WT, n=5; KO, n=5) and at 15 min after glucose injection (WT, n=6, KO, n=9); for some samples, insulin levels were below the threshold of detection. (F-G) Blood glucose levels during insulin tolerance tests (ITT) in female (WT, n=12; KO, n=13)

and male (WT, n=5; KO, n=7) mice at 24 weeks of age. Insulin was injected at a dose of 1 unit/kg body weight for both males and females. (H-I) Serum TG (H) and NEFA (I) levels during lipid tolerance tests (LTT) in male mice (WT, n=12; KO, n=15-16) at 23 weeks of age.

**Table 4.** Body weight, blood glucose, and organ weights from WT and myonectin-KO mice. All mice were euthanized after 2-4 h food removal in the morning. At the time of sacrifice, LFD-fed males and females were 35 weeks old, and HFD males and females were 39 weeks old. For LFD-fed males, N= 6 WT and 8 KO for kidney and heart weights. Values that are statistically significant (\*  $P < 0.05$ ) are bolded and underlined.

mice had lower RER in the light cycle, and male KO mice had significantly reduced physical activity in the dark cycle and over a 24-hr period (**Tables 5 and 6**). Because myonectin is also upregulated after an acute bout of exercise (28), we provided the WT and KO mice with a voluntary running wheel in the metabolic cages in a separate experiment. No major genotypic differences in either sex were observed (**Table 7**).

**Table 6.** Indirect calorimetry, physical activity, and food intake analysis of male mice fed a control low-fat diet (LFD). At the time of the study, mice were 27 weeks of age. Mice were given 2 days to acclimate to the metabolic cages. “*Ad-libitum*” data were collected on the third day. Mice were denied access to food but had free access to water on day 4 (“fasting” data), and “re-feed” data were collected on day 5 when mice regained free access to food. Values that are statistically significant (\*P<0.05) are bolded and underlined.

**Table 7.** Indirect calorimetry, physical activity, and food intake of myonectin-KO and WT mice (age 30 weeks) with access to a voluntary running wheel. Mice were given 4 days to acclimate to the metabolic cages and become accustomed to using the running wheel. Data were collected on day 5.

To assess whether myonectin deficiency alters carbohydrate metabolism, glucose tolerance tests (GTT) were performed. The rate of glucose uptake in peripheral tissues in response to glucose injection was not different between genotypes of either sex (**Fig. 2C,D**). The magnitude of insulin secretion in response to a rise in blood glucose during GTT did not differ between genotypes in males (**Fig. 2E**). We also performed insulin tolerance tests (ITT) to assess insulin action in peripheral tissue. The rate of glucose disposal in response to a bolus of insulin did not differ between genotypes of either sex (**Fig. 2F,G**). We previously showed that recombinant myonectin infusion promotes lipid uptake in mice (28). To test whether myonectin deficiency affects the ability of mice to handle an acute lipid load, we performed lipid tolerance tests. Overnight-fasted mice were orally gavaged with a bolus of emulsified intralipid, and serum lipid levels were measured over time to assess the rate of lipid uptake and clearance by peripheral tissues. No genotypic differences were observed in the rate of clearance of serum TG or NEFA (**Fig. 2H,I**). Aside from physical activity in the *ad-libitum* fed state or during refeeding, our data indicate that

myonectin is dispensable for whole-body carbohydrate and lipid metabolism under basal conditions.

### **Minimal impact of myonectin deficiency on carbohydrate metabolism in the context of obesity**

We next determined whether myonectin is required for a proper response to metabolic stress. A separate cohort of male and female WT and KO mice was challenged with a high-fat diet (HFD), beginning at 5 weeks of age, to induce obesity and insulin resistance. We performed the same sets of metabolic tests as in the control LFD-fed cohorts to determine whether myonectin deficiency exacerbates or improves the pathophysiological phenotypes associated with diet-induced obesity and insulin resistance. Body weight and body composition did not differ between genotypes of either sex (**Fig. 3A,B**). Despite no difference in overall fat mass, the gonadal fat pad was larger in myonectin-KO female mice relative to WT littermates (**Table 4**). Indirect calorimetry analyses indicated no differences in metabolic rate, physical activity, or energy expenditure between genotypes of either sex under *ad-libitum* fed conditions, or during a 24-h fast and 24-h re-feed (**Tables 8-9**). However, we noted that *ad-libitum* fed female KO mice had significantly reduced food intake in the light cycle (**Table 8**). In the refeeding phase following a fast, female KO mice had reduced food intake and lower RER in the dark cycle; the reduction in food intake was also observed over the 24-hr refeed period. In contrast to female mice, the only difference seen in KO male mice was reduced RER in the light cycle in the *ad-libitum* fed state (**Table 9**). Myonectin-deficient female mice also showed a modest impairment in the rate of glucose uptake in peripheral tissues in response to glucose or insulin injection (**Fig. 3C,F**). Myonectin-deficient male mice, however, were indistinguishable from WT littermates in glucose and insulin tolerance

**Figure 3. There are no overt carbohydrate metabolism phenotypes in the myonectin-KO mice fed a high-fat diet.** (A) Body weights of female (WT, n=8; KO, n=8) and male (WT, n=12-13; KO, n=16) mice over time. Mice were weaned at 3.5 weeks of age onto a standard chow diet. At 5 weeks of age, the diet was switched to a high-fat diet (Research Diets). (B) Body composition analysis of female (WT, n=7; KO, n=8) and male (WT, n=12; KO, n=16) mice at 28 weeks of age. (C) Blood glucose levels during intraperitoneal glucose tolerance tests (ip-GTT) in 18-week-old female mice (WT, n=8; KO, n=8). (D) Blood glucose levels during oral-GTT in 19-week-old male mice (WT, n=12; KO, n=12). (E) Serum insulin levels in male mice at 0 min before glucose gavage (WT, n=11; KO, n=9) and at 15 min after glucose gavage (WT, n=12; KO, n=11); for some samples, insulin levels were below the threshold of detection. (F-G) Blood glucose levels during ITT in female (WT, n=7; KO, n=8) and male mice (WT, n=11; KO, n=15) at 23 weeks of age. Insulin was injected at a dose of 1.2 units/kg body weight for female mice and 1.5 units/kg body weight for male mice. \*  $P < 0.05$

**Table 8.** Indirect calorimetry, physical activity, and food intake analysis of female mice fed a high-fat diet (HFD). At the time of the study, mice were 30 weeks of age. Mice were given 3 days to acclimate to the metabolic cages. “*Ad-libitum*” data were collected on the fourth day. Mice were denied access to food but had free access to water on day 5 (“fasting” data), and “re-feed” data were collected on day 6 when mice regained free access to food. Values that are statistically significant (\*P<0.05) are bolded and underlined.

### High-fat diet (Male)

**Table 9.** Indirect calorimetry, physical activity, and food intake analysis of male mice fed a high-fat diet (HFD). At the time of the study, mice were 30 weeks of age. Mice were given 3 days to acclimate to the metabolic cages. “*Ad-libitum*” data were collected on the fourth day. Mice were denied access to food but had free access to water on day 5 (“fasting” data), and “re-feed” data were collected on day 6 when mice regained free access to food. Values that are statistically significant (\*P<0.05) are bolded and underlined.

tests (**Fig. 3D,G**). The magnitude of insulin secretion in response to glucose injection during the glucose tolerance test did not differ between genotypes in males (**Fig. 3E**). Together, these results indicate that myonectin deficiency has minimal impact on whole body carbohydrate metabolism in the pathophysiological context of diet-induced obesity.

### **Impact of myonectin deletion on hematologic parameters**

Myonectin (also referred to as erythroferrone) plays important roles in linking stress erythropoiesis and hepatic iron mobilization in response to blood loss or anemia by suppressing hepcidin expression in liver (37, 38). Here, under basal non-stressed conditions, myonectin deficiency did not alter any blood parameters, including hemoglobin level, hematocrit, and population counts of lymphoid and myeloid cell types in male mice (**Table 10**), consistent with previous findings (38). Interestingly, under basal conditions when mice were fed a control low-fat diet, female mice lacking myonectin had significantly elevated total white blood cell counts as well as lymphocyte counts (**Table 10**). Although diet-induced obesity can adversely affect multiple cell types in the immune system (69), metabolic stress from a high-fat diet did not alter any of the blood parameters in myonectin-deficient mice of either sex relative to control WT littermates (**Table 10**). Liver hepcidin expression was also indistinguishable between WT and KO mice (**Fig. 4**). Thus, myonectin is not required for iron homeostasis under conditions where stress erythropoiesis is not induced.

### **Myonectin deletion impairs lipid handling in diet-induced obese male mice**

Although HFD-fed female WT and myonectin-KO mice had similar rates of lipid clearance following an oral lipid gavage (**Fig. 5**), male KO mice exhibited significant impairment

**Table 10.** Complete blood count of WT and myonectin-KO mice. At the time of sample collection, LFD-fed mice were 20 weeks of age, HFD-fed females were 22 weeks of age, and HFD-fed males were 26 weeks of age. Platelet counts were omitted from 1 WT and 2 KO LFD-fed females and 2 KO LFD-fed males due to the presence of platelet clumps in the sample. Values that are statistically significant are bolded and underlined. Abbreviation: RBC: red blood cell count, HGB: hemoglobin, HCT: hematocrit, MCV: mean corpuscular (erythrocyte) volume, MCH: mean corpuscular hemoglobin, MCHC: mean corpuscular hemoglobin concentration, RET: reticulocyte count, PLT: platelet count, WBC: white blood cell count, NEUT: neutrophil count, LYMPH: lymphocyte count, MONO: monocyte count, EO: eosinophil count, BASO: basophil count. \*  $P < 0.05$ , \*\*  $P < 0.01$

**Figure 4. Myonectin WT and KO male mice fed a high-fat diet do not differ in liver hepcidin expression.** Hpcidin mRNA expression in livers isolated from high-fat fed male mice sacrificed at 36 weeks of age in a postprandial state (WT, n=10; KO, n=17).

**Figure 5. Myonectin WT and KO female mice fed a HFD do not differ in lipid tolerance.** Serum triglyceride (TG; A) and non-esterified free fatty acid (NEFA; B) levels in mice during lipid tolerance tests (LTT) in female mice (WT, n=8; KO, n=8) at 24 weeks of age.

in uptake of triglyceride and free fatty acids from the circulation compared to WT littermates (**Fig. 6**). The impaired lipid clearance phenotype following lipid loading was confirmed in two additional independent cohorts of HFD-fed mice. Mice develop insulin resistance after exposure to a high-fat diet for a short period (1-4 weeks), whereas more pronounced differences in body weight gain occur after longer exposure to high-fat feeding (70). Because lipid tolerance was different between WT and KO male mice fed an HFD, we sought to determine whether insulin resistance due to HFD is sufficient to impair lipid disposal in response to oral lipid gavage. In contrast to chronic high-fat feeding, relatively short exposure to an HFD for 4 weeks did not alter lipid tolerance in myonectin-deficient mice compared to WT littermates (**Fig. 7**). This result suggests that excess adiposity from chronic high-fat feeding is necessary to alter lipid handling capacity in myonectin-null animals.

**Figure 6. Impaired lipid tolerance in myonectin-KO male mice fed a high-fat diet.** (A) Serum triglyceride (TG) and (B) non-esterified free fatty acids (NEFA) during lipid tolerance test (LTT) in male mice (WT,  $n=12$ ; KO,  $n=16$ ) at 17 weeks of age. \*  $P < 0.05$ , \*\*  $P < 0.01$ , \*\*\*  $P < 0.001$ .

**Figure 7. Insulin resistance alone is insufficient to induce impaired lipid clearance phenotype in myonectin-KO male mice fed a high-fat diet for only 4 weeks.** Serum triglyceride (TG; A) and non-esterified free fatty acids (NEFA; B) levels in male mice during lipid tolerance tests (LTT) at 9 weeks of age (WT, n=13; KO, n=9).

### Impact of myonectin deficiency on metabolic response to high-fat feeding later in life

Diet-induced obese mice in our studies were exposed to HFD beginning at 5 weeks of age, which corresponds to adolescence. To determine whether myonectin is required for metabolic flexibility in adult animals, we exposed another cohort of mice to HFD after they reached 21 weeks of age. After switching from standard chow to HFD for 12 weeks, mice were assessed by several tolerance tests. Body weight and glucose and insulin tolerance did not differ between genotypes of either sex (**Fig. 8A-G**). No differences in lipid tolerance were noted between WT and KO female mice (**Fig. 8H,I**). Male myonectin-KO mice, however, exhibited reduced capacity to clear serum TG from the circulation following an oral lipid gavage (**Fig. 8J,K**). The magnitude of difference between genotypes in lipid tolerance was smaller in this older cohort of myonectin-deficient male mice as compared to younger cohorts (Figure 6). These results indicate that the severity of the lipid tolerance phenotype is contingent upon the age at which mice are exposed to the metabolic stress of high-fat feeding.

**Figure 8. Body weight analysis, and glucose, insulin, and lipid tolerance in WT and myonectin-KO mice exposed to a high-fat diet later in life.** Mice were weaned onto a standard chow diet and switched to a high-fat diet at 21 weeks of age. (A) Body weight measurements over time of female (WT,  $n=14$ ; KO,  $n=15$ ) and male (WT,  $n=8$ ; KO,  $n=14$ ) mice. (B,D) Blood glucose levels during glucose tolerance tests (GTT) in female (WT,  $n=14$ ; KO,  $n=15$ ; B) and male (WT,  $n=8$ ; KO,  $n=13$ ; D) mice at 36 weeks of age. (C) Serum insulin levels during GTT in female mice at time 0 before glucose injection (WT,  $n=10$ ; KO,  $n=12$ ) and at 15 min after glucose injection (WT,  $n=14$ ; KO,  $n=15$ ); for some samples, insulin levels were below the threshold of detection. (E) Serum insulin levels during GTT in male mice at time 0 before glucose injection (WT,  $n=8$ ; KO,  $n=14$ ) and at 15 min after glucose injection (WT,  $n=7$ ; KO,  $n=14$ ); for some samples, insulin levels were below the threshold of detection. (F) Blood glucose levels during insulin tolerance tests (ITT) in female mice at 43 weeks of age (WT,  $n=13$ ; KO,  $n=15$ ). (G) Blood glucose levels

during ITT in male mice at 41 weeks of age (WT, n=7; KO, n=13). Insulin was injected at a dose of 1.2 units/kg body weight for female mice and 1.5 units/kg body weight for male mice. (H-I) serum TG (H) and NEFA (I) levels during lipid tolerance tests (LTT) in female mice at 34 weeks of age (WT, n=12-14; KO, n=15). (J-K) serum TG (J) and NEFA (K) levels during LTT in male mice at 34 weeks of age (WT, n=8; KO, n=13-14). \*  $P < 0.05$

### **Elevated postprandial VLDL-triglyceride levels in myonectin-deficient male mice**

Although myonectin deficiency impairs the capacity to acutely handle orally delivered emulsified intralipid, it is unclear whether myonectin is required for the proper handling of dietary lipids in a postprandial state following physiologically normal *ad-libitum* feeding. To test this, HFD-fed male mice were fasted overnight and then given free access to food for 2 h. Blood samples were taken before and after re-feeding, and serum lipid levels were measured. While fasting serum TG levels were similar between WT and KO mice, postprandial serum TG levels were significantly higher in myonectin-KO mice upon re-feeding following a fast (**Fig. 9A**). Fasting and postprandial serum NEFA and cholesterol levels were not different between genotypes (**Fig. 9B,C**). Food intake did not differ between WT and KO mice (**Table 9**), thus differences in calorie intake cannot explain differences in postprandial serum TG levels. Fractionation of pooled postprandial serum revealed that myonectin-KO male mice had significantly elevated and larger very-low-density lipoprotein (VLDL)-triglyceride particle levels compared to WT males (**Fig. 9D**). Lipoprotein cholesterol profiles showed that the size, but not the amount, of HDL-cholesterol was larger in the myonectin-KO animals (**Fig. 9E**). These data indicate that myonectin is required for proper postprandial handling of dietary triglyceride derived from normal *ad-libitum* feeding of an HFD.

**Figure 9. Higher postprandial VLDL-triglyceride levels in myonectin-KO male mice fed a high-fat diet.** Serum triglyceride (TG; A), non-esterified free fatty acids (NEFA; B), and cholesterol (C) levels in male mice after an overnight 14-h fast (“fasted”) or after an overnight fast followed by *ad-libitum* re-feeding for 2 h (“refed”). Mice (36 weeks of age) were euthanized after re-feeding for tissue collection. 2 WT mice did not eat during the re-feed period as assessed by 1) no increase in serum TG levels over fasting levels, and 2) an empty stomach. Therefore, re-fed data from these mice were not included in the analysis. Fasted: WT, n=12; KO, n=17. Re-fed: WT, n=10; KO, n=17. (D-E) Re-fed serum samples from 10 mice of each genotype were pooled and subjected to FPLC fractionation to separate lipoprotein species. Triglyceride (D) and cholesterol (E) levels were measured in each fraction. \*  $P < 0.05$

### **Loss of myonectin does not affect intestinal lipid absorption and secretion**

Several mechanisms could affect lipid clearance from the circulation. For example, elevated serum TG levels in myonectin-KO mice after oral lipid gavage or *ad-libitum* feeding could be due to enhanced intestinal lipid absorption and/or greater secretion of TG-rich chylomicrons by the enterocytes. To test this, overnight-fasted mice were injected with poloxamer 407, a detergent that inhibits lipoprotein lipase (LPL) activity, preventing lipid uptake in peripheral tissue. After 1 h, mice were orally gavaged with intralipid. Accumulation of serum TG over time reflects intestinal lipid absorption and subsequent secretion of TG-rich chylomicrons. No differences in the kinetics of serum TG rise were noted between HFD-fed WT and KO mice (**Fig. 10A**). Alternatively, impaired lipid uptake into peripheral tissues could result in the elevated TG levels seen in KO animals. LPL plays a major role in the cellular uptake of lipids derived from circulating lipoprotein particles; the enzyme is located on the surface of endothelial cells in most tissues and hydrolyzes TG to liberate free fatty acids, which can then be taken up by peripheral tissues (71). We therefore measured whole-body LPL activity in post-heparin sera collected from mice in the postprandial state. As we previously observed, a 2-h *ad-libitum* feeding following an overnight fast was sufficient to induce a difference in serum TG between genotypes; the heparin-displaceable total LPL activity, however, was not different between WT and myonectin-KO mice (**Fig. 10B,C**).

### **Myonectin deletion alters adipose fat storage and lipid accumulation in liver**

We next sought to determine whether myonectin deficiency alters lipid storage in peripheral tissues. Although HFD-fed WT and KO mice had similar body weights and body composition (**Fig. 3A,B**), the distribution of fat among tissues was altered. We noted that the KO

**Figure 10. WT and myonectin-KO male mice fed a high-fat diet do not differ in intestinal lipid absorption or postprandial heparin-releasable serum lipase activity.** (A) Serum TG levels over time during intestinal lipid absorption/secretion assay in male mice at 21 weeks of age (WT,  $n=12$ ; KO,  $n=17$ ). (B) Serum TG levels measured in serum samples collected after 2 h of re-feeding but before heparin injection in male mice (WT,  $n=12$ ; KO,  $n=17$ ). mice (39-week-old) had significantly increased fat mass (both visceral and subcutaneous fat depots) and a modest reduction in liver weight (**Fig. 11A-C** and **Table 4**). Liver histology revealed a marked reduction in steatosis in KO mice relative to WT littermates (**Fig. 11D**). Quantification of lipids also revealed significantly reduced hepatic TG content and lower cholesterol levels (**Fig.**

**Figure 11. Myonectin deficiency alters lipid distribution in male mice fed a high-fat diet.** WT and myonectin-KO mice were euthanized at 39 weeks of age after a 2–4-h fast in the morning. Unless otherwise specified, data in this figure are from analysis of WT (n=12) and KO (n=16) male mice. The wet weight of liver (A), visceral (gonadal) fat pad (B), and subcutaneous (inguinal) fat pad (C) are presented along with (D) representative images of H&E stained liver sections from WT and KO mice. (E-F) Quantification of TG (E) and cholesterol (F) levels in livers. (G) Western blot analysis of Perilipin 2. Two separate gels were run, each with WT (n=6) and KO (n=8) samples. PLIN2 levels were first normalized to HSC70 levels from the same gel and then normalized to the average WT value. Data were then combined from both gels for analysis. (H-I) Representative images of H&E stained epididymal white adipose tissue (eWAT) and inguinal white adipose tissue (iWAT) sections from WT and KO male mice. (J) Quantification of adipocyte size in eWAT sections (WT, n=5; KO, n=5). (K) Quantification of adipocyte size in iWAT sections (WT, n=4; KO, n=5).  $*$   $P < 0.05$ ,  $**$   $P < 0.01$

**11E,F**). Consistent with the histologic data and hepatic TG content, the lipid droplet-associated protein perilipin 2 was also correspondingly reduced in myonectin-KO livers (**Fig. 11G**). Histologic analysis of visceral (epididymal) white adipose tissue (eWAT) and subcutaneous (inguinal) white adipose tissue (iWAT) indicated significantly larger adipocytes in myonectin-KO animals (**Fig. 11H,I**); this was further confirmed by cell size quantification (**Fig. 11J,K**). Differences in adipocyte cell size were more pronounced in the visceral fat depot (eWAT). These data suggest that myonectin plays a role in lipid partitioning between tissues and its deficiency promotes adipose tissue lipid storage and reduces lipid accumulation in liver.

### **Myonectin deletion alters multiple liver metabolite levels**

Given the striking differences in lipid partitioning between adipose and liver of HFD-fed WT and KO animals, we measured circulating lipids from blood collected at the same time as tissue samples as shown in Fig. 11. Serum TG, NEFA, and  $\beta$ -hydroxybutyrate levels were similar between HFD-fed WT and KO male mice; serum cholesterol levels, however, were lower in myonectin-KO animals (**Fig. 12A-D**). To explore the genotypic difference in hepatic fat accumulation, we also performed unbiased metabolomics analysis to assess global changes in liver metabolites. Of the 642 metabolites quantified, only a small subset (32 in total) of metabolites significantly differed between WT and KO mice (**Fig. 12E**). Our data indicate that HFD-fed myonectin-KO male mice had elevated secondary bile acids, as well as increased levels of metabolites involved in one-carbon metabolism. Interestingly, the hepatic level of imidazole propionate, a molecule reported to induce insulin resistance (72), was also significantly elevated in myonectin-KO male mice; however, this did not impair insulin sensitivity in male mice as measured by glucose and insulin tolerance tests (**Fig. 3D,G**). In addition to metabolite profiling,

**Figure 12. Steady-state serum and liver metabolite levels in WT and myonectin-KO male mice fed a high-fat diet.** Sera and livers were harvested from mice (39 weeks old) 2-4 h after food removal (A-E). Quantification of serum triglyceride (TG; A), non-esterified free fatty acids (NEFA; B), cholesterol (C), and ketones ( $\beta$ -hydroxybutyrate; D) (WT,  $n=12$ ; KO,  $n=16$ ). (E) All liver metabolites that were significantly different ( $p < 0.05$ ) between WT ( $n=10$ ) and myonectin-KO ( $n=10$ ) male mice. \*  $P < 0.05$

we performed extensive quantitative PCR to assess the expression of genes involved in lipid synthesis and catabolism in liver and adipose tissue. Of the major genes involved in lipid synthesis and oxidation and lipoprotein and iron metabolism, there were no significant differences in the expression levels between genotypes in the liver or two major fat depots (**Fig. 13**). However, for genes involved in bile acid metabolism, the expression of *Cyp7a*, the rate limiting

**Figure 13. Expression of lipid metabolism genes in liver and visceral and subcutaneous fat depots of myonectin-KO and WT male mice fed a high-fat diet.** (A-C) Expression of lipid metabolism genes in liver (A), epididymal white adipose tissue (eWAT; B), and inguinal white adipose tissue (iWAT; C) as measured by quantitative real-time PCR (WT, n=12; KO, n=15-16). (D-F) Expression of genes involved in

lipoprotein metabolism (D), bile acids and cholesterol metabolism (E), and heme and iron metabolism (F) in liver as measured by quantitative real-time PCR (WT, n=12; KO, n=16). enzyme in bile acid synthesis, was significantly upregulated in the liver of myonectin-KO male mice (**Fig. 13E**).

### **Myonectin deficiency does not alter hepatic VLDL-TG secretion or fat oxidation**

Since steady-state levels of metabolites (after 2 h of food removal) and gene expression could not fully explain the differential lipid accumulation in adipose and liver, we tested specific pathways of lipid flux *in vivo*. Reduced hepatic steatosis in HFD-fed KO mice could be due to increased hepatic VLDL-TG secretion. To test this, mice were first fasted for 4 h, beginning at 2 h into the light cycle, to ensure the absence of food-derived circulating chylomicrons secreted by enterocytes; in this physiological state, most of the circulating TG is likely derived from VLDL-TG particles secreted from liver. Mice were next injected with poloxamer 407 to inhibit lipid uptake in peripheral tissue. Thus, the accumulation of serum TG over time reflects hepatic VLDL-TG secretion. This experiment revealed no differences between WT and KO mice, indicating that hepatic VLDL-TG secretion cannot account for the reduced hepatic TG accumulation in myonectin-deficient male mice (**Fig. 14A**). Alternatively, enhanced hepatic fat oxidation can result in lower hepatic TG content. While not a direct measure of fat oxidation in liver, serum ketones are good proxies because ketogenesis in the liver is biochemically linked to fat oxidation (73); hence, circulating ketone levels correspond to the extent of hepatic fat oxidation. Circulating ketones ( $\beta$ -hydroxybutyrate) did not differ between WT and KO mice in either the fasted or fed

state, indicating that there were no differences in hepatic fat oxidation between genotypes (**Fig. 14B**).

**Figure 14. Hepatic VLDL secretion and fat oxidation in myonectin-KO and WT male mice fed a high-fat diet.** (A) Serum TG levels over time during hepatic VLDL secretion assay in male mice at 20 weeks of age (WT, n=13; KO, n=17). (B) Serum levels of  $\beta$ -hydroxybutyrate in male mice at 36 weeks of age. Serum was collected after an overnight fast (“fasted”), and also collected upon overnight fast followed by refeeding (“refed”). Fasted: n=12 WT, 17 KO; refed: n=10 WT, 17 KO. Two WT mice did not eat during the re-fed period; therefore, refed serum data from these mice were not included in the analysis.

### Myonectin deficiency does not alter adipose tissue lipolysis

Given that myonectin-KO mice had greater adiposity, decreased adipose tissue lipolysis could account for this phenotype. Although recombinant myonectin treatment does not affect *ex vivo* lipolysis in white adipose tissue explants (28), the impact of its deficiency on adipose lipolysis *in vivo* is unknown. To test this, mice were injected with a  $\beta_3$ -adrenergic receptor agonist (CL316,243) to stimulate lipolysis following a 5-h fast. CL-stimulated lipolysis was assessed by measuring serum glucose, glycerol, and NEFA before and 15 min post-injection; no differences were observed between WT and KO mice (**Fig. 15**). Our data thus indicate that both basal (no changes in steady-state serum NEFA levels; **Fig. 12B**) and stimulated lipolysis were not altered in mice lacking myonectin.

**Figure 15. Myonectin-KO and WT male mice fed a high-fat diet do not differ in their capacity for stimulated white adipose tissue lipolysis.** (A) Blood glucose, (B) serum glycerol, and (C) serum NEFA levels in male mice at 24 weeks of age during an experiment assessing  $\beta_3$ -adrenergic agonist (CL316,243)-stimulated lipolysis (WT, n=12; KO, n=17).

### **Myonectin-deficient male mice have higher postprandial LPL activity in the subcutaneous fat depot**

Increased lipid uptake into adipocytes could result in greater adiposity. The capacity for peripheral tissues to take up circulating lipid is largely dependent on LPL whose activity is regulated in a tissue-specific and metabolic state-dependent manner (71). In WAT, LPL expression is downregulated during fasting to divert lipid away from adipose to other oxidative tissues. In contrast, LPL activity is activated in WAT postprandially to promote lipid uptake and storage. We therefore measured LPL activity in subcutaneous (iWAT) and visceral (eWAT) fat depots obtained from HFD-fed mice euthanized after 2 h of food removal or in a postprandial state (overnight fast followed by 2 h *ad-libitum* feeding). LPL activity was significantly increased in iWAT from KO mice relative to WT controls, but only in the postprandial state (**Fig. 16A,B**). Increased LPL enzymatic activity was not due to increased expression of LPL mRNA or protein in the iWAT from KO animals (**Fig. 16C-E**). Angiopoietin-like proteins and apolipoproteins are known to regulate LPL activity (74). We therefore assessed the expression of known LPL inhibitors

**Figure 16. Postprandial lipoprotein lipase (LPL) activity in the subcutaneous (inguinal) fat depot is increased in myonectin-KO male mice fed a high-fat diet.** (A) LPL activity in epididymal white adipose tissue (eWAT: WT, n=12; KO, n=16) and inguinal white adipose tissue (iWAT: WT, n=12; KO, n=15) from mice euthanized at 39 weeks of age following a 2–4-h fast in the morning. (B) LPL activity in eWAT and iWAT from mice (WT, n=10; KO, n=17) euthanized at 36 weeks of age after 2-h re-feeding following an overnight fast. (C) LPL mRNA expression in the same eWAT (WT, n=10; KO, n=16) and iWAT (WT, n=10; KO, n=15) samples as (B). (D-E) Western blot analysis of LPL in the same iWAT samples as in (B). Two separate gels were run, one with 6 WT and 8 KO samples, and the other with 4 WT and 8 KO samples. LPL levels were first normalized to HSC70 levels from the same gel, then normalized to the average WT value. Data were then combined from both gels for analysis (WT, n=10; KO, n=16) (E). Images from one gel are shown (D). \*\*\*  $P < 0.001$

(*Angptl3*, *Angptl4*, *Angptl8*, and *ApoC3*) and activators (*ApoC2*, *ApoA4*, and *ApoA5*) in the same fat tissue samples as well as in liver. We also examined the level of *Fxr* mRNA, the transcriptional regulator of angiopoietin-like proteins and apolipoproteins, as well as *Gpihbp1* and *Vldlr* that are important for translocation of LPL to the cell surface. At the mRNA level, no significant genotypic

differences were observed for these transcripts in WAT and liver (**Fig. 17A-C**). We also measured protein levels of ANGPTL3 and ANGPTL4, two of the major LPL inhibitors, in fasting serum as well as the postprandial serum samples; their protein levels were also not significantly different between genotypes (**Fig. 17D-E**).

**Figure 17. Serum levels and expression of genes involved in regulating lipoprotein lipase (LPL) activity or transcytosis in different fat depots and liver of myonectin-KO and WT male mice fed a high-fat diet.** (A-C) Expression of LPL regulators, as measured by quantitative real-time PCR, in inguinal white adipose tissue (iWAT; A), epididymal white adipose tissue (eWAT; B), and liver (C) from mice sacrificed at 36 weeks of age after 2-h re-feeding following an overnight fast (WT, n=10; KO, n=15-17). Relative gene expression was first normalized to *36b4*, then normalized to the average WT value. (D-E) Serum levels of ANGPTL3 (D) and ANGPTL4 (E) in myonectin-KO and WT male mice after an overnight fast (“fasted”) or following 2 h of re-feeding (“Refed”). Fasted: n=12 WT, 17 KO; refed: n=10 WT, 17 KO. Two WT mice did not eat during the re-fed period; therefore, refed serum data from these mice were not included in the analysis.

## DISCUSSION

We used a genetic loss-of-function mouse model to determine whether myonectin is required physiologically to maintain metabolic homeostasis. Under basal conditions where mice were fed a control low-fat diet (LFD) comparable to standard chow, myonectin was largely dispensable for regulating whole-body carbohydrate and fat metabolism, consistent with a recent report (62). However, there is one notable phenotype in male mice fed a control LFD: myonectin deficiency significantly reduced physical activity in the *ad-libitum* fed state, as well as in the refed (post-prandial) state following a 24 hour fast. In the fasted state where mice typically have heightened foraging behavior, physical activity level was not significantly different between genotypes; thus, there appears to be a physiological state-dependent change in ambulatory and total physical activity in the KO animals. We speculate that myonectin may modulate, directly or indirectly, a central pathway controlling physical activity in male mice between two opposing (fed and fasted) metabolic states. Of note, the reduced physical activity seen in myonectin-KO male mice is not the result of a functional deficit in the skeletal muscle since the capacity for an exhaustive sprint or endurance run was not significantly different between genotypes, nor were the pre- and post-exercise blood glucose, lactate, NEFA, or ketone levels. The ability of skeletal muscle and liver to replenish their glycogen stores following exercise (with or without glucose gavage post exercise) was also not significantly different, indicating that myonectin is not required for the metabolic response or adaptation to a single bout of exercise. It appears that myonectin is also dispensable for physiologic adaptation to chronic voluntary exercise. When indirect calorimetry analyses were conducted in WT and KO mice with access to a running wheel, we observed no significant differences in metabolic rate, food intake, or the amount of voluntary

exercise (wheel running) between genotypes of either sex. Similarly, a recent report indicates that myonectin is not required for normal heart function under normal, non-stressed conditions (29).

In the pathophysiological context of obesity and insulin resistance induced by a high-fat diet (HFD), we observed two significant and notable phenotypes related to lipid metabolism in the myonectin-deficient animals. First, myonectin-KO mice displayed an impaired ability to handle an acute oral lipid load. Second, lipids appear to be partitioned differentially between adipose and liver; specifically, myonectin-KO male mice had strikingly reduced triglyceride accumulation in liver and, in parallel, a significant increase in adiposity due to greater lipid storage in hypertrophied adipocytes. These two lipid phenotypes in KO animals are sex-dependent. Apart of developing mild insulin resistance and a bigger gonadal fat pad, myonectin-KO female mice fed an HFD were largely indistinguishable from WT littermates with respect to whole-body lipid metabolism. It is known that female mice on a C57BL/6 genetic background are much less susceptible to diet-induced obesity (75, 76). Many studies (77), including our previous studies (54-56) and the present study, reinforce the importance of sex as a biological variable that can influence the impact and phenotypic outcomes of a given genotype. Intriguingly, although our current study and previous findings (62) do not support a major role for myonectin in regulating glucose metabolism, recent reports suggest that circulating myonectin in human blood is correlated with insulin resistance, impaired glucose metabolism, and type 2 diabetes (60, 61). Whether myonectin plays a causal role in human carbohydrate metabolism and insulin sensitivity, distinct from rodents, remains to be determined.

We previously showed that myonectin infusion lowers serum lipid levels in mice and, when given to cultured hepatocytes and adipocytes, also promotes lipid uptake into cells (28). Additionally, ingestion of lipid via oral gavage can upregulate myonectin expression (28). Based

on these previous findings, we hypothesized that myonectin deficiency would result in impaired lipid clearance following an oral lipid load. Indeed, myonectin-KO male mice exhibited a significantly greater rise in both serum TG and NEFA levels following an oral lipid challenge relative to WT littermates, a functional deficit we observed in multiple independent cohorts of HFD-fed male KO mice. Several mechanisms could account for the observed phenotype: 1) impaired lipid clearance and uptake by peripheral tissues as hypothesized, and/or 2) increased intestinal lipid absorption and chylomicron secretion. We ruled out the latter as the cause of the lipid intolerance seen in myonectin-deficient animals. To determine lipid uptake by peripheral tissues, we focused on LPL activity since this enzyme is a major determinant of lipid clearance in extrahepatic tissues (71). The biggest difference in serum lipid levels between genotypes was seen at 2 h after oral lipid gavage or 2 h post-feed following a fast; we therefore quantified the total heparin-displaceable LPL activity in the serum 2 h post-feeding. Although there were no significant genotypic differences in total lipase activity, we could not rule out potential differences in LPL-dependent lipid uptake between WT and KO mice. Of note, both WT and KO mice converged on the same baseline lipid levels 4 h after oral lipid gavage. Thus, the observed significant differences at earlier time points likely reflect differences in the kinetics of lipid uptake rather than the overall capacity for lipid disposal in peripheral tissues. For example, relative to WT littermates, the overall LPL activity may be lower in myonectin-KO mice shortly after oral lipid gavage, reflecting slower activation of the enzyme in response to altered nutritional state, which would result in a much greater rise in serum triglyceride at 0-2 h post-gavage that we observed. At later time points total LPL activity in KO mice may reach the same maximum level attained in WT mice, reflecting the marked decline in serum triglyceride observed in KO mice at 2-4 h post-gavage, leading to the same baseline lipid levels between genotypes 4 h after oral lipid challenge.

Hence, it is possible that when we measured total LPL activity at 2 h post-feeding, LPL activity in WT mice was in the process of decreasing back to baseline and the activity in the KO animals was increasing to its maximal level. Future studies will help to determine the total heparin-displaceable LPL activity at different time points after oral lipid challenge.

The second major phenotype observed in myonectin-KO male mice is a significant difference in lipid distribution between liver and adipose tissue. We observed significantly greater adipocyte hypertrophy, due to greater fat storage in lipid droplets, in both the visceral and subcutaneous fat depots of HFD-fed KO mice. Parallel to increased adiposity, we observed a striking reduction in fat accumulation in the liver of myonectin-deficient animals. Several mechanisms could underlie this phenotype, including liver-specific processes, adipose-specific processes, or a combination of both. Reduced hepatic steatosis could be a consequence of either increased fat oxidation, increased VLDL secretion, decreased lipid uptake from circulation, and/or decreased *de novo* lipogenesis. Serum ketones ( $\beta$ -hydroxybutyrate), a good proxy for liver fat oxidation (73), were not significantly different between WT and KO mice in either fed or fasting states, thus ruling out hepatic fat oxidation as the cause for reduced steatosis. We also ruled out enhanced hepatic VLDL-triglyceride secretion as a contributing factor to reduced fatty liver. Although lipid uptake and fatty acid synthesis have not been directly measured, our liver metabolite profiling, in addition to extensive PCR quantification of genes involved in hepatic lipid metabolism, does not suggest any differences in these two processes.

Interestingly, despite a striking reduction in ectopic lipid accumulation in liver, myonectin-KO male mice did not exhibit better hepatic glucose metabolism profiles relative to WT littermates; fasting blood glucose levels (dominated by hepatic gluconeogenesis) and insulin tolerance tests did not reveal any significant differences between genotypes. While fatty liver—

resulting from excessive ectopic fat deposition in the obese state— is frequently associated with impaired hepatic insulin action (as reflected in greater hepatic glucose output) (4), these two phenomena appear to be uncoupled in myonectin-KO animals. Intriguingly, one of the liver metabolites that was significantly upregulated in myonectin-KO male mice is imidazole propionate. This molecule, thought to be produced from histidine by gut microbiota, was recently reported to be elevated in obese humans with type 2 diabetes and when given to mice can induce insulin resistance (72). While it seems that diabetic humans have a relatively wide range of imidazole propionate concentrations relative to non-diabetic controls, the level of upregulation (2-3 fold) we observed in the myonectin-KO mice is not sufficient to disrupt normal insulin signaling as indicated by a lack of significant differences in fasting blood glucose, as well as glucose and insulin tolerance.

An alternative explanation for the reduced fat accumulation seen in myonectin-KO liver could be secondary to changes in fat storage in adipose tissue, leading to reduced ectopic lipid deposition in other organs and tissues. Enlarged adipocytes seen in our myonectin-KO mice could result from decreased lipolysis, increased lipid uptake and storage, decreased fat oxidation, and/or increased *de novo* lipogenesis. We ruled out reduced adipose lipolysis as a cause of increased adiposity, as neither basal nor  $\beta_3$ -adrenergic agonist stimulated lipolysis was significantly different between WT and KO mice. LPL activity was measured in adipose tissue as a proxy for the capacity for lipid uptake. Intriguingly, LPL activity was significantly greater in the subcutaneous (inguinal) fat depot of KO mice relative to WT littermates in the postprandial state. Increased fat uptake into adipocytes via LPL may, in part, account for the increase in adiposity and adipocyte cell size. However, this appears to be fat depot-specific; we did not observe a significant increase in LPL activity in the visceral (gonadal) fat of KO animals. Although fat oxidation and synthesis in adipose

tissue were not directly measured in this study, none of the lipid synthesis or catabolism genes we considered were significantly different in their expression levels between WT and KO mice. What accounts for the increased LPL activity seen in the iWAT of myonectin-KO mice is presently unclear, since none of the known regulators (angiopoietin-like proteins and apolipoproteins) of LPL activity and transcytosis were different in their expression or serum protein levels between WT and KO animals.

In summary, we provide here a detailed analysis of the metabolic consequences of myonectin deletion in a genetic mouse model. Whereas myonectin is largely dispensable for whole-body glucose metabolism, it plays an important role in regulating local and systemic lipid metabolism. Loss of myonectin causes lipid intolerance in response to oral lipid loading and it alters lipid distribution between adipose and liver. Thus, in addition to regulating stress erythropoiesis in the context of blood loss (38), myonectin/erythroferrone is also a secreted metabolic regulator of fat metabolism in the physiological context of diet-induced obesity. Future studies will help pinpoint the mechanisms by which myonectin controls fat metabolism in a tissue-specific manner, and the receptor (currently unknown) through which it exerts its biological functions.

### **Peer-Reviewed Publications:**

Rodriguez, S.; **Little, H.C.**; Shepard, B.D.; Wolfe, A.; Cheema, M.U.; Jandu, S.; Woodward, O.M.; Talbot Jr., C.C.; Berkowitz, D.E.; Pluznick, J.L.; Wong, G.W. (2019) Late-onset renal hypertrophy and dysfunction in mice lacking CTRP1. *FASEB J.* Under review.

**Little, H.C.**; Rodriguez, S.; Lei, X.; Tan, S.Y.; Stewart, A.N.; Sahagun, A.; Sarver, D.C.; Wong, G.W. (2019) Myonectin deletion promotes adipose fat storage and reduces liver steatosis. *FASEB J.* [Epub ahead of print]

**Little, H.C.**; Tan, S.Y.; Cali, F.M.; Rodriguez, S.; Lei, X.; Wolfe, A.; Hug, C.; Wong, G.W. (2018) Multiplex quantification identifies novel exercise-regulated myokines/cytokines in plasma and in glycolytic and oxidative skeletal muscle. *Mol. Cell. Proteomics*. **17**, 1546 – 1563. (PMCID: PMC6072542)

Lei, X.; Seldin, M.M.; **Little, H.C.**; Choy, N.; Klonisch, T.; Wong, G.W. (2017) C1q/TNF-related protein 6 (CTRP6) links obesity to adipose tissue inflammation and insulin resistance. *J. Biol. Chem.* **292**, 14836-14850. (PMCID: PMC5592665)

Petersen, P.S.; Lei, X.; Wolf, R.M.; Rodriguez, S.; Tan, S.Y.; **Little, H.C.**; Schweitzer, M.A., Magnuson, T.H.; Steele, K.E.; Wong, G.W. (2017) CTRP7 deletion attenuates obesity-linked glucose intolerance, adipose tissue inflammation, and hepatic stress. *Am. J. Physiol. Endocrinol. Metab.* **312**, E309-E325. (PMCID: PMC5406989)

Tan, S.Y.; **Little, H.C.**; Lei, X.; Li, S.; Rodriguez, S.; Wong, G.W. (2016) Partial deficiency of CTRP12 alters hepatic lipid metabolism. *Physiol. Genomics*. **48**, 936-949. (PMCID: PMC5206390)

Rodriguez, S.; Lei, X.; Petersen, P.S.; Tan, S.Y.; **Little, H.C.**; Wong, G.W. (2016) Loss of CTRP1 disrupts glucose and lipid homeostasis. *Am. J. Physiol. Endocrinol. Metab.* **311**, E678-E697. (PMCID: PMC5241556)

Zeng, H.; **Little, H. C.**; Tiambeng, T.; Williams, G. A.; Guan, Z. (2013) Multifunctional Dendronized Peptide Polymer for Effective siRNA Delivery. *J. Am. Chem. Soc.* **135**, 4962-4965.

#### **Poster Presentations:**

**Little, H.C.**; Tan, S.Y.; Lei, X.; Rodriguez, S.; Petersen, P.S.; Wong, G.W. (2018) Myonectin Deficiency Alters Lipid Metabolism in High Fat Fed Mice. Abstract for poster presentation, Keystone Symposia on Organ Crosstalk in Obesity and NAFLD. Keystone, CO, January 21, 2018.

**Little, H.C.**; Tan, S.Y.; Lei, X.; Rodriguez, S.; Petersen, P.S.; Wong, G.W. (2017) Myonectin Deficiency Alters Lipid Metabolism in High Fat Fed Mice. Abstract for poster presentation, Navigating Lipid Research in Baltimore. Baltimore, MD, May 5, 2017.

**Little, H.C.**; Tan, S.Y.; Lei, X.; Rodriguez, S.; Petersen, P.S.; Wong, G.W. (2016) Myonectin Deficiency Alters Lipid Metabolism in High Fat Fed Mice. Abstract for poster presentation, Kern Lipid Conference. Vail, CO, August 8, 2016.

#### **Service and Leadership:**

|            |              |   |  |
|------------|--------------|---|--|
| Co-founder | 2016-present | Graduate Student Peer Mentoring Program | Johns Hopkins University, School of Medicine |
|------------|--------------|---|--|

(Co-founded a peer mentoring program that facilitates organized peer support among graduate students by hosting monthly discussions and workshops focused on common hardships faced in graduate school)

|             |           |        |  |
|-------------|-----------|--------|--|
| Lead mentor | 2013-2017 | Thread | Non-profit organization, Baltimore, MD |
|-------------|-----------|--------|--|

(Mentored an at-risk Baltimore City high school student for four years; oversaw three other mentors of the same student and delegated roles and tasks based on each mentor's strengths)
